SUBCLINICAL MITRAL DISEASE

CHAIRMAN'S ADDRESS

MERRILL C. SOSMAN, M.D.

BOSTON

Mitral stenosis is almost invariably acquired and is practically always the result of rheumatic fever. It is most frequently found between the ages of 15 and 40 and is more common in females than males by a ratio of three to two.

Mitral insufficiency may be either organic or relative. Relative mitral insufficiency is secondary to dilatation of the left ventricle, which may occur from a number of causes. Organic mitral insufficiency is also almost always the direct result of rheumatic fever. The former is of more serious import as it usually occurs in a dilated heart. Organic mitral insufficiency may exist for years without impairing the efficiency of the heart but often is followed by mitral stenosis or subacute bacterial endocarditis. Although mitral insufficiency may persist alone for many years, very commonly the signs of insufficiency disappear, stenosis develops or the patient may succumb to subacute bacterial endocarditis, in all too frequent eventuality.

From a study of the pathologic physiology consequent on mitral stenosis or mitral insufficiency it is evident that dilatation of the left auricle will almost invariably ensue in both conditions. It is reasonable to conclude, therefore, that careful roentgen study could be of help in the diagnosis of mitral disease by demonstrating the dilated left auricle. If mitral stenosis alone is present there will be no enlargement of the left ventricle. If, as much more frequently occurs, the stenosis is associated with mitral insufficiency, there will also be enlargement of the left ventricle.

The diagnosis of mitral stenosis can be made by several different methods, particularly auscultation, roentgen examination and electrocardiography. Other signs may suggest the presence of the condition or may contribute to the diagnosis but are rarely pathognomonic. The most widely used and the most accurate method is careful auscultation. In the early stages of the process the trained ear will hear a snapping first sound, which suggests the diagnosis, and a short pre-systolic or middiastolic rumbling murmur which is practically pathognomonic. It may be necessary to have the patient go through a short period of vigorous exercise to bring out the characteristic late diastolic rumble or it may be heard only when the patient is lying on the left side. In this stage it may easily be overlooked. In more advanced degrees of mitral stenosis the murmur may fill all of diastole and is more easily heard. Usually, of course, there is an accompanying systolic murmur.

The next most important method of confirming the diagnosis is the demonstration of the dilated left auricle fluoroscopically or roentgenographically. This is second in importance only to the characteristic diastolic murmur in the opinion of Parkinson.¹

The third observation of critical importance is less frequent but may lead to the correct diagnosis in a doubtful case. This is the presence of a broad, flattened P wave in the electrocardiogram, especially if right axis deviation is also present. This should lead one to make a presumptive diagnosis of mitral stenosis even in the absence of the characteristic diastolic murmur, as in case 4.

The typical auscultatory observations may be absent or overlooked (a) in the early stages of the process, when the change in the diameter of the valve orifice is slight and the murmur absent or very faint, and (b) in the advanced stages of the process, particularly when there is heart failure. The velocity of the blood flow through the mitral valve produces the murmur, so that if there is great dilatation of the chambers the velocity may be quite slow and the murmur very faint or absent. In this type of heart the murmur may reappear as the failure disappears. This is particularly true when there is auricular fibrillation with heart failure.

In the great majority of the cases of mitral stenosis, roentgen examination will demonstrate dilatation of the left auricle. This is best seen in the right anterior oblique position and may be of sufficient degree to displace the esophagus posteriorly and sometimes to the patient's right. In the postero-anterior view the change in the cardiac contour may be less marked and less characteristic. There may be only a straightening of the normally concave "waist" of the heart on the left border, a contour not typical of mitral disease. In the more advanced cases the left contour presents the double convexity of the dilated pulmonary artery and tip of the dilated left auricle between the aortic knob and the left ventricular contour (figs. 1 and 2). Fluoroscopic examination is much more valuable in the study of heart disease than are x-ray films. The observer is better able to separate the different chambers by their alternate pulsations and can note abnormal pulsations. He may bring out changes in heart size and relations by different phases of respiration. More important still, he may select the best amount or degree of rotation to study the contours of the various chambers and vessels and may note the effect of changed contour on neighboring structures such as the esophagus. Fluoroscopy is the only reliable method of finding, locating and identifying areas of intracardiac calcification during life, a finding which may be of critical importance in the diagnosis.

The fluoroscopic examination of a patient with mitral valvular disease, therefore, should reveal: 1. A straightening or a double convexity of the midportion of the

Read before the Section on Radiology at the Ninety-First Annual Session of the American Medical Association, New York, June 13, 1940.

1. Parkinson, John: Enlargement of the Heart (Lumleian Lecture). *Lancet* 1: 1337 (June 13), 1391 (June 20) 1936.

left cardiac contour. 2. Dilatation of the left auricle posteriorly, best shown in the right anterior oblique position. The convex curve of the dilated auricle is located in the middle third of the cardiac shadow and may obscure the middle third of the posterior mediastinal space. 3. Widening of the base of the heart in the right anterior oblique view, due to the combination of enlarged pulmonary conus anteriorly and dilated left auricle posteriorly.

Fluoroscopy may also show: 4. Displacement of the barium-filled esophagus posteriorly with moderate to marked dilatation of the auricle, best shown during the expiratory phase but most reliable when also present during inspiration. 5. Dilatation of the pulmonary vessels at the lung roots due to stasis in the pulmonary circulation. These vessels do not pulsate as in Ayerza's disease and patent ductus arteriosus. They may be considerably dilated and congested without producing physical signs or symptoms. 6. Hypertrophy of the right ventricle, seen best in the exaggerated left anterior oblique view, which reveals a ledge or shoulder projecting anteriorly. 7. Narrowing of the precardiac space in the lateral view, with a greater amount of the heart in contact with the sternum than normal and (8) a hypoplastic aortic knob, in cases in which the mitral stenosis was acquired in childhood. Marked dilatation of the pulmonary artery may partly obscure the aortic knob, making it seem hypoplastic by comparison. The real hypoplasia is thought to be due to a decreased volume of blood from the left ventricle, in turn due to the mitral stenosis.

In advanced or long standing mitral valvular disease, the left auricle may be so dilated that it will displace the left bronchus upward and may even compress it. This may result in dyspnea, cough, atelectasis or obstructive emphysema of the left upper lobe. In other advanced cases the left auricle may extend far to the right and make up a part or even all of the right cardiac contour, sometimes simulating the contour seen with tricuspid insufficiency. When a double contour on the right is seen, the upper convexity will be due to the left auricle, which will lie more posteriorly than the lower one. If the tube is shifted from side to side the upper curve will be seen to move in the opposite direction more than the lower one, indicating its more posterior position. This is the principle of parallax, used in locating metallic foreign bodies. Usually there is an easily perceptible difference in pulsation, the two chambers contracting and expanding alternately. This is due to the systolic expansion of the left auricle as a result of the mitral insufficiency. A dilated descending branch of the right pulmonary artery may simulate a dilated left auricle projecting to the right and may even show a transmitted systolic pulsation immediately following the auricular contraction of the lower (right auricular) convexity. The true character of this upper curve may be recognized by watching it carefully while rotating the patient to the left, and by noting the point of origin and the other branches of the artery on the film, where it is wedge shaped, base up.

Of these signs the dilated left auricle is the only important or critical one: the others are supportive and confirmatory. Of still greater value and, in my experience, absolutely pathognomic, is the demonstration of calcified areas in the mitral valve. Calcification in the injured mitral valve is found in the majority of cases at autopsy but is unfortunately not visible fluoroscopically in more than 10 per cent of the patients during life. This is in striking contrast to aortic stenosis,

in which the majority will have deposits of calcium large enough to be readily demonstrable under the fluoroscope.²

These diagnostically important intracardiac deposits of calcification are easy to find and easy to differentiate if a few simple rules are followed. They are most easily located fluoroscopically. The observer's eyes must be thoroughly prepared by at least fifteen minutes in a completely darkened room. A radiolite wrist watch or a Pirie photometer can be used to test accommodation for night vision. With the eyes properly accommodated, the usual screen examination is carried out and then the observer narrows the fluoroscopic aperture to a few square centimeters and looks through the heart, searching for dark dancing shadows. The intracardiac calcium deposits all show a to and fro movement with systole and diastole, and those in the valves may have an excursion of 2 or 3 centimeters, sometimes in an elliptic or triangular course. The calcified aortic and mitral valves are found under a line along the auriculoventricular sulcus, which is usually about 45 degrees from the horizontal. The auriculoventricular junction is easily identified on the left border. The patient should be rotated slightly to the left, so that the calcified areas will not be hidden by the spine. The patient should take a deep inspiration and hold it, so that the underlying pulmonary markings will be immobile and not confusing. This also helps by intensifying the contrast due to the distention of the lung. If the heart has the "mitral" configuration, the calcified areas are nearer the apex than with the "aortic" configuration, where they are found nearer the base. This is due to the dominance of the dilated auricles in the first type of heart and of the hypertrophied ventricle in the "aortic" type. If a calcified valve is found a fairly accurate guess can be made as to which valve is calcified by considering the shape of the heart. A more reliable and more accurate means of differentiating between the calcified aortic and mitral valves is to rotate the patient to the opposite side (left anterior oblique), where the mitral valve will be found to be in the posterior third of the heart shadow, while the aortic valve will be found in the middle third. The pulmonic and tricuspid valves are very rarely calcified and do not enter into the differential diagnosis as a rule. A frequent source of error, however, is calcification of the mitral annulus fibrosus. This is frequently quite massive and is the most easily demonstrable of the three. However, the calcified annulus is usually either U shaped or J shaped or O shaped, and it is more homogeneous than the irregular mulberry-like calcification in the valves themselves. Its movements are similar to those of the calcified mitral valve but its clinical significance is nil. It occurs only as a senile change, usually in persons over 60 years of age, and is often associated with arcus senilis and calcification of the intervertebral disks. There is no dilatation of the left auricle with calcification of this ring, as the mitral valve is not involved and its function is not affected.

The other intracardiac calcifications are not ordinarily confused with calcification in the valves. Calcification large enough in amount to be visible fluoroscopically has been found in (a) the coronary arteries,³ (b) the pericardium, (c) the myocardium, such as calcified infarcts, (d) the endocardium, particularly of the auri-

cles, and (e) rarely in one of the benign tumors. The latter has not yet been found during life; the others have all been noted during life and subsequently confirmed at autopsy.

There is no special apparatus required to demonstrate these calcified valves, just the regular fluoroscope with a 5 inch gap, 5 milliamperes of current, a small fluoroscopic aperture and a screen of fine grain and high intensity like the type B fluoroscopic screen. The sensitization of the eyes for fifteen minutes is probably the most important step in the procedure.

If one finds, therefore, a dilated left auricle and calcification in the mitral valve, one can make an unequivocal diagnosis of mitral stenosis. The presence of calcification in the mitral valve indicates in my opinion the rheumatic etiology, as I have not found this degree of calcification in the mitral valve to be due to either syphilitic or atherosclerotic processes. I feel that this is true also in the majority of cases of aortic stenosis with calcification. If the appearances are those of a dilated left auricle with the collateral observations already noted and without demonstrable calcification of the mitral valve, the diagnosis of mitral stenosis is highly presumptive, even in the absence of other physical signs.

Fig. 1 (case 1).—Seven foot film of the heart showing general cardiac enlargement and the fulness in the middle third of the left cardiac contour very suggestive of mitral disease.

Fig. 2 (case 1).—Right anterior oblique film showing marked dilatation of the left auricle posteriorly, displacing the esophagus in a characteristic concavity, highly suggestive of mitral stenosis.

Fig. 3 (case 1).—Spot film taken at 30 inch distance, 200 milliamperes, one twentieth second, showing an irregular mass of calcification in the mitral valve (arrows), unequivocal evidence of mitral stenosis, and posterior displacement of esophagus (single arrow).

For many years my associates and I have regularly made a fluoroscopic examination of all patients sent to us for examination of the heart and nearly all of those sent for chest examination. In addition we make a fluoroscopic examination of the chest in all gastrointestinal examinations.

During this time, but more particularly since 1935 when we found an unsuspected mitral stenosis in one of our technical staff, we have recorded for purposes of "clinically undiagnosed cases of mitral mitral disease." This is admittedly an erroneous and etymologically incorrect label. If strictly interpreted it could mean "mitral disease under the bed." What we do mean, I think, is amply explained by the preceding discussion, that is, patients with mitral disease whose condition was clinically undiagnosed before roentgen examination. We soon found that such patients could be grouped or classified in several subdivisions. For our own purposes of record we have termed them class A, B and C. The class A group is a small one. These patients have unequivocal roentgen signs of mitral disease, but the clinical observations are either absent or inconclusive. The diagnosis could not be made at the time of exami-

nation without the roentgen signs. Cases 1 and 2 reported herewith are typical examples of this group.

Class B is the largest group and includes the patients with undoubted mitral disease in whom the physical signs of the disease were overlooked by one or more competent physicians before the roentgen examination. The appearances by fluoroscopic and film examinations were quite definite, and careful study by our cardiologist, Dr. S. A. Levine, brought out the definite signs of mitral disease and confirmed the diagnosis. The diagnosis could have been made by the cardiologist without the roentgen examination. A third group, class C, includes those patients with the roentgen findings compatible with mitral disease but not characteristic of it and with no clinical or other observations to corroborate the diagnosis. Patients in this group are being followed to see if they subsequently develop typical clinical signs of mitral disease or other conditions to explain the abnormal roentgen appearances. No doubt we should add a fourth group, class D, to include those patients in whom the clinical signs of mitral disease are quite definite but the roentgen appearances are either inconclusive or negative. This group is quite small. Roesler⁴ says that dense mediastinal

adhesions may account for the lack of dilatation of the left auricle in those cases.

The list of conditions which may cause dilatation of the left auricle and thus simulate mitral disease is usually given as follows: Thyrotoxicosis, emphysema, pneumoconiosis, fibrosis of the left upper lobe, beriberi, congenital heart disease, especially patency of the ductus arteriosus and pulmonic stenosis, scoliosis of the spine to the right, and pleuropericardial adhesions. Tumors in the auricle close to the valve could of course cause mechanical stenosis of the valve and might in time give rise to the usual roentgen configuration of mitral disease.⁵ In my experience most of the foregoing conditions either fail to simulate the appearance of mitral disease or do so only but rarely, particularly emphysema, pneumoconiosis, pulmonary fibrosis, scoliosis and extra-pericardial adhesions. As to the others, thyrotoxicosis in my experience rarely causes changes in cardiac contour which would simulate mitral disease except in failing hearts with auricular fibrillation. Patent ductus

arteriosus can and does simulate mitral disease roentgenographically and may cause dilatation of the left auricle as is reported by Eppinger and Burwell⁶ in this symposium. Similarly it may give the clinical signs and murmurs of mitral disease, as occurred in one of the cases included in the report by Dr. Gross.⁷ The most frequent cause of error in the diagnosis of mitral disease in our series is in heart failure from any cause, particularly with cardiac dilatation and auricular fibrillation. The dilated left auricle seen in these conditions may actually be due to relative mitral regurgitation or to stasis in the atonic fibrillating auricle. Sussman and Woodruff⁸ have shown that fibrillation of the auricles is rarely followed by dilatation of the auricles unless complicated by valvular disease. As a matter of actual practice in fluoroscopic examination we rarely see patients with the degree of cardiac failure just noted, and those with thyrotoxicosis can usually be differentiated by the hyperactivity of the heart and by the absence of the normal sinus arrhythmia. Moderate degrees of left auricular dilatation may be present in ambulatory patients with heart failure due to nonvalvular lesions such as beriberi, anemia or nephritis, but in general I agree with Parkinson¹ that definite dilatation of the

of mitral stenosis as there would be in the early diagnosis of cancer or of pulmonary tuberculosis. The treatment would not be any different nor would it presumably have any different effect. The value of such studies must lie therefore in the difference in prognosis, with a possible change in our ideas as to the latent or inactive period in potential heart disease—that period between the first infection with rheumatic fever and the onset of symptoms or the discovery of physical signs of acquired valvular heart disease. The difficult differential diagnosis in this stage is between no heart disease at all with a normal prognosis and acquired mitral valvular disease, which is of quite serious import and which automatically carries with it a bad prognosis as to length of life.

REPORT OF CASES

CASE 1.—D. G., an Italian laborer aged 38, was first seen in the medical outdoor department of the Peter Bent Brigham Hospital on Oct. 7, 1938, complaining of shortness of breath on exertion for about one year, and epigastric pain, thought to be due to peptic ulcer. He was accordingly referred to us for gastrointestinal examination and during the routine fluoroscopy of his chest an enlarged heart of mitral configuration was noted (figs. 1 and 2). On looking through the heart with the fluoro-

Fig. 4 (case 2).—Seven foot film of the heart showing general cardiac enlargement and the double convexity in the middle third of the left cardiac contour suggesting mitral stenosis.

Fig. 5 (case 2).—Right anterior oblique film showing marked dilatation of the left auricle (arrows) projecting beyond the anterior border of the spine.

Fig. 6 (case 3).—Seven foot film of the heart showing slight cardiac enlargement, a straight left border without convexities, and fairly marked dilatation of the pulmonary vessels. Patient was symptomless at time.

left auricle is one of the most certain signs of mitral stenosis, and this is particularly true in the absence of heart failure.

The accuracy of our clinical diagnoses in acquired valvular heart disease is quite high, particularly in the hands of trained cardiologists, but most of these patients are in advanced stages of the disease and many are soon confirmed at autopsy. Our accuracy in the early stages of the disease is open to question, as there is often a long latent period between a given attack of rheumatic fever and the discovery of mitral stenosis. The process must inevitably have been present and gradually progressing during the latent period when no murmurs, or only a systolic murmur, were present. Mitral stenosis does not appear suddenly; it is a slow gradual process. It is quite possible, therefore, that the routine use of the fluoroscope by a trained observer may be of aid in the earlier diagnosis of mitral stenosis. There is little of therapeutic value in the earlier diagnosis

scope, we found a calcified area in the region of the mitral valve (fig. 3) with the characteristic dancing movements during the cardiac cycle. The left auricle was dilated posteriorly and there was bilateral pulmonary congestion. Neither at that time nor subsequently in the cardiac clinic were physical signs of mitral stenosis heard, but Dr. Levine concurred in the diagnosis after seeing the x-rays and the report of fluoroscopy.

No history of rheumatic fever could be elicited, but he had suffered from frequent nosebleeds as a child—one of the stigmas commonly associated with rheumatic fever. The patient was studied thoroughly in the medical ward from Sept. 14 to Sept. 27, 1939, and again no definite diagnosis of mitral stenosis could be made except by roentgen examination.

Additional observations in the ward were noncontributory and are given here only for the sake of completeness. The urine was normal with a specific gravity varying from 1.012 to 1.016; no sugar or albumin was found. Blood examination showed hemoglobin 105 per cent, red blood cells 5,220,000, white blood cells 9,100, polymorphonuclears 75 per cent, hematocrit 42 per cent. The serologic reaction was negative. The phenol-sulfonphthalein excretion was 70 per cent in two hours. Gastric analysis revealed hyperacidity. The spinal fluid was normal, including the colloidal gold curve, protein determinations and manometric readings. The icteric index was 5. The vital capacity was 2,300 cc. The basal metabolic rate was —8 per cent. The sedimentation rate was 30 mm. an hour. The venous pressure was 65 mm. of water. The circulation time (decholin

method) was 18 seconds. An electrocardiogram showed normal curves. Scratch sensitivity tests showed increased sensitivity to several materials. A gastrointestinal series was normal. Cholecystograms were normal. Dr. Romano, on analyzing the patient, found a rather profound psychoneurosis.

The patient has been seen several times since his discharge from the hospital, his condition essentially unchanged, with no definite signs or symptoms of cardiac disability except for the occasional paroxysmal and nocturnal attacks of dyspnea, which were thought not to be of cardiac origin. There was no improvement in his condition nor has there been any worsening. The last note on his record is the rather cryptic one that in the spring of this year (1940) he had borrowed \$300 and returned to Italy, leaving his wife and children in Boston.

CASE 2.—R. D., a married woman aged 37, Jewish, was admitted to the hospital Jan. 11, 1936, because of pain in the right leg of three days' duration. Physical examination revealed an enlarged heart, with auricular fibrillation but no significant murmurs. Dr. Levine felt that she had an enlarged heart with auricular fibrillation and thought that she might have mitral valvular disease because of the presumed embolus to the right femoral artery and other episodes suggesting peripheral emboli. Roentgen examination (figs. 4 and 5) confirmed the suspicion of mitral stenosis, revealing fairly marked cardiac enlargement both to the right and to the left, with marked dilatation of the left auricle obscuring the posterior mediastinal space and displacing the esophagus backward and to the right. Pulmonary congestion was also present. No calcification of the mitral valve could be demonstrated but the diagnosis of mitral stenosis appeared to be quite definite without it. Dr. Levine stated that he could only suspect the presence of a mitral stenosis in the absence of the characteristic murmur, but with the roentgen observations the diagnosis seemed quite certain.

The patient's response to therapy was not satisfactory and she died in June 1936, presumably from a pulmonary infarction. Unfortunately an autopsy was not obtained.

These two patients are both listed in our records as class A: ones in whom the diagnosis of mitral stenosis could not be made without the roentgen examination. There are others in the same group, each presenting a particular problem of his own, but none any less definite than case 2 or more positive than case 1, in which we feel that the diagnosis of mitral stenosis is unequivocal in spite of absence of clinical signs and symptoms.

There are many more patients listed in class B but a detailed presentation of their vital statistics would be of no particular value to the informed reader. It is common knowledge that a particular diagnosis can be made more easily and more accurately by the man who

As one example typical of the whole group of class B patients I cite case 3:

CASE 3.—H. R., an unmarried woman aged 36, a nurse technician, complained of ease of fatigue, loss of weight, shortness of breath on exertion and troublesome cough at times. Fearing pulmonary tuberculosis, she asked for an x-ray examination of her chest. We found (fig. 6) no evidence of primary pulmonary disease but we did note considerable pulmonary congestion chiefly around the hili and an abnormal contour of the heart shadow, with straightening of the left border, slight cardiac enlargement and definite dilatation of the left auricle posteriorly. No calcification of the mitral valve could be demonstrated, but we felt that the diagnosis of mitral stenosis was highly presumptive.

A study of her past history revealed chorea at the age of 18, scarlet fever at the age of 19 and frequent attacks of tonsillitis during the past twelve years. She had been seen by several competent physicians in the past few years but they had not made the diagnosis of mitral stenosis. Dr. Levine, however, was able to detect the faint diastolic murmur characteristic of the disease and made the diagnosis without reservation. The patient had intermittent but progressive symptoms of cardiac failure during the succeeding three years and died in cardiac decompensation July 26, 1938. During her periods of decompensation the diastolic murmur would decrease in intensity and sometimes disappear.

CASE 4.—J. S. B., a man aged 33, was admitted to the hospital Jan. 16, 1940, in heart failure. There was no past history of rheumatic fever, but he had been told that he had heart murmur in childhood. He had suffered from shortness of breath for four years and had a series of small hemoptyses three years before admission. Following appendectomy one year before admission there were migratory joint pains which were considered to be due to rheumatic fever. Dr. Levine has seen the patient four years before, at which time he found a systolic murmur only, but he made a presumptive diagnosis of mitral stenosis because of the electrocardiographic tracings, which showed a broadened flattened P wave (fig. 7).

Physical examination on admission showed him to be in heart failure, fibrillating, with rales at both bases, fluid at the right base, moderate venous engorgement, slight pitting edema of the lower extremities and a markedly enlarged tender liver. The first sound at the apex was snapping in character; there was a grade 3 systolic murmur but no diastolic murmur could be heard.

X-ray examination (fig. 8) revealed marked cardiac enlargement, with marked dilatation of the left auricle, dilatation of the pulmonary vessels and moderate enlargement of the right ventricle and right auricle. Fluoroscopy showed a large mass of calcification in the region of the mitral valve. Our interpretation was "combined valvular heart disease, primarily mitral, with calcification of the mitral valve."

The patient did not respond well to therapeutic attempts and died the day following admission. Autopsy was refused.

COMMENT

Cases 3 and 4 are examples of mitral stenosis in which the diagnosis can be materially aided by x-ray examination. In case 3 the presumptive diagnosis was pulmonary tuberculosis but the correct diagnosis could

Fig. 8 (case 4).—Seven foot film of the heart showing marked cardiac enlargement both to the right and to the left, a double convexity on the left border and dilatation of the pulmonary vessels, suggesting combined valvular heart disease, primarily mitral.

Fig. 7 (case 4).—Upper curves show electrocardiograms of a normal patient. Lower set clearly indicates mitral stenosis. Note prominent broad topped and notched P waves (lead 2) and right axis deviation.

has the most interest and the most experience in that field. There is no doubt that many cases of mitral stenosis are overlooked in their earlier stages; in fact there must be a stage in most of the cases in which the condition is still latent and the diagnosis cannot be made by any means. We can only speculate at present as to whether or not the left auricle is already beginning to dilate when the diastolic murmur first becomes audible. Additional work is being done along these lines.

have been made by a competent cardiologist. It was easily made by fluoroscopic examination. In case 4 the electrocardiogram gave the first hint as to the correct diagnosis, and again it was easily verified by fluoroscopic examination. It could have been made (and was in case 3) by x-ray examination independent of the history and physical examination. It could have been suspected from her constitutional type, as she was of Irish descent, with red hair, a fair complexion and many freckles. There had been a previously unexplained moderate hypochromic anemia for years, variable in degree, and intermittent menorrhagia, all frequent concomitants of rheumatic heart disease in New England.

SUMMARY AND CONCLUSIONS

Mitral stenosis can be diagnosed in a high percentage of cases by careful roentgen examination, including fluoroscopy.

The demonstration of a calcified mitral valve is unequivocal evidence of mitral stenosis and also indicates its rheumatic etiology.

Dilatation of the left auricle without general cardiac enlargement is highly presumptive evidence of mitral stenosis.

The diagnosis of mitral stenosis can at times be made by roentgen examination even in the absence of characteristic physical signs—here called "subclinical mitral disease."

PROGNOSIS IN CARCINOMA OF THE RECTUM

A COMPARISON OF THE BRODERS AND DUKES METHODS OF CLASSIFICATION

ALBERT C. BRODERS, M.D.

LOUIS A. BUIE, M.D.

ROCHESTER, MINN.
AND

DONALD R. LAIRD, M.D.

PORTLAND, ORE.

In recent years a signal advance has been made in determining the operability of malignant lesions of the rectum and sigmoid, and methods have been evolved by which it is now possible to determine with fair accuracy the probable length of life of individuals following removal of such lesions. Operability can be determined by proctoscopic examination, digital examination of the terminal portion of the colon and bimanual examination of the pelvis. Much of prognostic significance may be learned by such methods, but little can be determined in this manner concerning length of life following radical removal of carcinoma.

A valuable single criterion by which the surgeon can usually decide, before operation, the probable length of life of a patient following radical extirpation of malignant lesions has been provided by one of us,¹ namely the numerical microscopic grading of such tumors. By using such a method the surgeon or pathologist is able to recognize certain cellular changes which are of sig-

nificance in determining operability, mortality and the probable period of survival following operation. The earliest study was made in 1920 on a series of 537 patients suffering from epithelioma of the lip. It was then that four grades of malignancy were described, but in 1925 this method of grading was altered so that grade 1 included those lesions in which from nearly 100 to 75 per cent of the cells are differentiated, grade 2 from 75 to 50 per cent, grade 3 from 50 to 25 per cent, and grade 4 from 25 to 0 per cent. The grading of carcinoma on a basis of cellular differentiation is a natural application of the general biologic principle that, as a cell becomes differentiated or specialized, its power to reproduce is decreased. One of us² said that "a carcinoma whose cells increase in geometric progression without differentiation beyond the point of reproduction would grow faster and be more malignant than one that caused a number of cells to differentiate beyond the point of reproduction."

The high power photomicrographs in figures 1 and 2 show the relative proportion of differentiated and undifferentiated cells in grades 1, 2, 3 and 4.

In grade 1 carcinomas the cells are columnar; the nuclei are not prominent and are smaller than in grade 2. They approach closely the appearance of normal mucous membrane. The low power arrangements of cells in the two grades may closely resemble each other.

In grade 2 the cells are less columnar and the nucleus forms a more prominent part of the cell. The nucleoli are relatively larger, and well formed acini are nearly always present.

In grade 3 the cells are larger and definitely round, and the nucleus takes up nearly all of the cell. Acini may be present but are usually poorly formed. The low power arrangement of cells may closely resemble that of grade 2, but when the majority of cells are large and rounded and the nuclei are nearly as large as the cell, the carcinoma should be graded 3.

In general, the cells in grade 4 lesions tend to be large, hyperchromatic and round and have dedifferentiated so far that they bear little resemblance to the cells of the colonic mucous membrane. Both the low power and the high power views reveal definite characteristics, and there is less chance of error in a consideration of these cells than in the cells of a grade 2 carcinoma. MacCarty³ has discussed the cytologic aspect of the carcinoma cell, and he stressed the volume relationship between the nucleolus, the nucleus and the whole cell in reparative regenerative cells and in malignant regenerative cells. He found that the nucleolar-nuclear area ratio varies from approximately 1:23 in malignant cells to 1:50 or more in reparative regenerative cells.

In 1926 Lockhart-Mummery⁴ adopted a method of classifying carcinoma of the rectum based on clinical and pathologic factors. He arranged his cases in three groups, as follows: class A, small movable lesions which did not appear to involve the muscular coat or the lymph nodes; class B, lesions which appeared to involve the muscular coat but were not fixed and the lymphatic involvement of which was not extensive, and class C, large growths which were fixed and in which there was evidence of extensive lymphatic involvement.

Dukes⁵ modified this arrangement so that in class A he included lesions which were definitely limited to the wall of the rectum without extrarectal extension or metastasis to lymph nodes. In class B he placed growths which had spread by direct extension to extrarectal tissues but had not invaded the lymph nodes. He considered all carcinomas in which metastasis was present in the regional lymph nodes to be in class C.

In 1933 Wood and Wilkie⁶ studied 100 resected specimens of carcinoma of the rectum, classified them according to the Dukes method and divided them histologically into four grades. Their method of histologic gradation was not that of Broders but was modified in that the grading was done on the low power arrangement of cells instead of the degree of differentiation of cells. They believed that the early stage of carcinoma is represented by a flattened plaque in the mucous membrane and that the least malignant tumors tend to grow toward the lumen and take on a papilliferous appearance. High grade tumors with deeply penetrating tendencies remain flat or have only moderately elevated margins. W. W. Mayo⁷ expressed the same opinion many years ago. Mucoid carcinomas with signet ring cells were believed to be the most malignant.

TABLE 1.—Comparison of Five Year Survival Rates According to Class of Lesion (Lockhart-Mummery, Dukes) in Five Different Investigations

Class of Patients	Gabriel, Dukes and Bussey 1935	Dukes 1936	Gordon-Watson 1938	Lockhart-Mummery 1938	Broders, Buie and Laird 1938
Number of patients surviving and traced	100	142	88	289	354
Percentage of patients alive 5 years after resection:					
Class A.....	83.3	86.6	82.7	66.3	79.2
Class B.....	54.5	56.0	55.2	46.8	39.0
Class C.....	14.3	20.9	13.3	25.4	18.7

In 1935 Gabriel, Dukes and Bussey⁸ made a study of thirty perineal and seventy perineo-abdominal excisions and grouped them according to the Dukes method of classification. They stretched the resected specimen on a frame and fixed it in 10 per cent solution of formaldehyde. All lymph nodes were measured, located on a drawing of the resected specimen, cut and examined histologically.

Gordon-Watson⁹ in 1938 divided eighty-eight specimens of carcinoma removed by perineal excision into classes according to the method of Dukes⁵ and reported the number of years each patient in the series had lived. In 1938 Lockhart-Mummery¹⁰ published the results of his personal experience with 388 patients treated by perineal excision and recorded the grades of growth according to the Dukes method, the immediate operative result and the length of life of each patient. In each of the aforementioned investigations the percentage of five year survivals, based on the patients who survived operation and were traced, was determined for each class, and these are shown in table 1.

A study of the work and the conclusions of these investigators prompted the present investigation. It was felt that by taking new specimens from resected growths and studying them according to both the Broders and the Dukes method a comparative study might bring forth interesting inferences and establish substantial conclusions. Accordingly, the records of all patients treated for carcinoma of the rectum and rectosigmoid at the Mayo Clinic during the years 1920, 1921, 1929 and 1930 were collected, and since only those instances in which radical resection of the tumor was performed would serve our purpose, all other records were deleted. Thus 432 records were found to fit all requirements. In addition, 250 cases, making a total

Fig. 1.—Section of a grade 1 carcinoma of the rectum (a); the cells are columnar; the nuclei are not prominent and are smaller than those in grade 2 lesions. They approach closely the appearance of normal mucous membrane (hematoxylin and eosin stain; slightly reduced from a photomicrograph with a magnification of 400 diameters). Section of a grade 2 carcinoma of the rectum (b); the cells are less columnar and the nuclei form a more prominent part of the cell. The nucleoli are relatively larger and are well formed; acini are often present (hematoxylin and eosin stain; slightly reduced from a photomicrograph with a magnification of 400 diameters).

of 682, in which only colostomy or exploration was performed were included for the study of auxiliary problems. A suitable follow-up procedure was established in order to gather information regarding the length of life of the patient following the operation.

Second, all pathologic specimens removed at operation were reexamined. A longitudinal incision was made, exposing the mucosal surface of the bowel, so that the conformation of the lesion would be disturbed as little as possible. A sketch was made to actual size of the plane surface of the lesion and the portion of ulcera-

tion. The position of the lesion was established by measuring and recording its distance above the external anal margin. Approximately every three sixteenths of an inch (5 mm.) for the full length of the specimen, incisions were carried transversely to the long axis of

scopically. Usually the first impression as to the degree of extension was unchanged by microscopic examination. One growth thought to be class B on gross inspection was changed to class A after microscopic examination (fig. 6). The blocks of tissue, identified by the patient's number, were frozen, sectioned and stained with hematoxylin and eosin. Some blocks of tissue from specimens obtained in 1920 and 1921 were immersed in a 3 per cent solution of ammonium hydroxide for twelve hours and were then replaced in 10 per cent solution of formaldehyde in order to improve staining qualities.

TABLE 2.—Distribution According to Histologic Grade of Malignancy (Broders) in 682 Cases, Comprising the Total Series Examined

Type of Surgical Treatment	Total Patients	Grade of Malignancy							
		1		2		3		4	
		Pa-tients	Per Cent	Pa-tients	Per Cent	Pa-tients	Per Cent	Pa-tients	Per Cent

Some form of resection.....	432	73	16.9	241	55.8	100	23.1	18	4.2
Total.....	682	123	18.0	370	54.2	150	22.0	39	5.7

Fig. 2.—Section of a grade 3 carcinoma of the rectum (a); the cells are larger and definitely round, and the nucleus occupies nearly all of the cell; acini, when present, are usually poorly formed (hematoxylin and eosin stain; slightly reduced from a photomicrograph with a magnification of 400 diameters). Section of a grade 4 carcinoma of the rectum b; the cells are usually large, hyperchromatic and round; they bear little resemblance to the cells of the mucous membrane of the colon (hematoxylin and eosin stain; slightly reduced from a photomicrograph with a magnification of 400 diameters).

the bowel from the serosal to the mucosal surface. By this means the thin slices hinged on the uncut mucous membrane, facilitating examination of lymph nodes (fig. 3). A sketch of a section of the specimen was made to show the depth of ulceration and the degree of penetration of the wall of the bowel by the carcinoma. Lymph nodes were frozen, sectioned and stained with Terry's neutral polychrome methylene blue. Those nodes that were seen to be free from metastasis were represented in the sketch by clear circles, and those that were involved were indicated by filled in circles. If one lymph node was found to contain metastasis, no further nodes were examined microscopically. One or more blocks of tissue were taken at the points of deepest penetration of the carcinoma, and their relative positions were indicated on the sketches. Photographs of the gross specimens in classes A, B and C are shown in figures 4 and 5. The Dukes classification of the growth was recorded. In a few instances, classification was deferred until the block could be examined micro-

scopically. Third, the sections were studied microscopically by the method of Broders and the grade was recorded on each slide. According to the Dukes method, the drawings were examined, verified histologically and recorded on the slide. This information, with the sketch, was then added to a card on which the other pertinent data had been previously recorded. In this way the grading was established without knowledge of any other facts in the case.

In a few instances, involvement of lymph nodes found on the first examination was not found on reexamination. When this occurred the original report was accepted.

Fig. 3.—Illustrating the manner in which specimens in this series were cut for examination of lymph nodes.

DISTRIBUTION BY GRADE

Table 2 shows the distribution according to Broders' gradation in 682 cases in which surgical treatment had been administered. Table 3 compares the grading by different authors in resected growths. Close agreement is apparent and indicates that, if the Broders method is followed carefully, results should be consistent. The reason for the difference between the series of Broders

and the present series may be understood by comparing the distribution of grade 4 in 1920 and 1921 with grade 4 in 1929 and 1930. It should be remembered also that this is a comparison of grades of resected specimens and not of distribution in general. In 1920

Fig. 4.—Carcinoma of the rectum (a), class A, grade 4; the carcinoma apparently did not penetrate the musculature of the rectum at any point; carcinoma of the rectum (b), class B, grade 2; the carcinoma has penetrated the musculature in several places.

and 1921 grade 4 represented 7.2 per cent of 152 resected specimens, and in 1929 and 1930 only 2.5 per cent of 280 specimens were classified in this group. This difference was the result of the fact that in 1929

TABLE 3.—*Percental Distribution of Grades of Malignancy—2,210 Resected Neoplasms Reported in Four Investigations*

Series	Total Cases Reported	Percentage in				Col- loid
		Grade of Malignancy				
		1	2	3	4	
Broders, Buie and Laird	432	16.9	55.8	23.1	4.2	
Rankin and Broders.....	598	17.6	50.0	23.5	8.9	
Broders.....	580	14.6	51.8	24.5	9.1	
Dukes.....	600	6.0	54.0	26.0	2.0	12.0

and 1930 some surgeons did not favor the surgical removal of grade 4 lesions because of the unfavorable outlook for the patient. The discrepancy between the percental distribution in the Duke's series and ours can be explained by two factors. First, Duke¹¹ failed to follow accurately the Broders¹² method of grading. In his article "Histological Grading of Rectal Cancer" he said:

The system of grading tumors described by Broders supplies such a standard. . . . It can be applied easily to malignant growths of the adenocarcinoma type provided one bases the judgment on a general survey and not on a single field of the microscope. Actually the decision as to the grade of malignancy is more dependent on the arrangement of the cells than on the relative number of so-called undifferentiated cells.

11. Dukes, Cuthbert: Histologic Grading of Rectal Cancer, Proc. Roy. Soc. Med. 30: 371-376 (Feb.) 1937.

12. Footnotes 1 and 2.

This accounts for the comparatively low percentage of the grade 1 growths. Many grade 1 lesions have the general histologic arrangement of the average grade 2 growths, and it is only by considering the relative number of dedifferentiated cells and their degree of dedifferentiation that the proper distinction can be made. The second factor is that Duke¹¹ graded colloid carcinoma separately. We do not believe that this is necessary.

There is difference of opinion as to the degree of malignancy of colloid carcinoma. Some observers believe that formation of mucus is a sign of functional

TABLE 4.—*Operative Mortality and Three and Five Year Survival Rates According to Class of Lesion (Lockhart-Mummery and Dukes)—426 Traced Patients Out of 432 Operated On*

Class	Patients Operated On	Patients Traced	Operative Mortality,* per Cent	Percentage of	
				Patients Alive After 3 Years	Patients Alive After 5 Years
A	116	115	12	76.5	69.6
B	121	120	16	51.6	32.2
C	195	191	29	31.5	14.6

* All patients who died within a month in the hospital are included in the operative mortality.

differentiation of the carcinoma cell and that carcinomas showing mucoid degeneration possess a relatively low degree of malignancy. Others believe that mucoid carcinomas, which are the most undifferentiated structurally, secrete the most mucinous material. Raiford¹³ stressed the importance of distinguishing between true primary mucoid carcinoma and mucoid degeneration. He preferred the term "mucoid carcinoma" to "colloid

Fig. 5.—Carcinoma of the rectum, class C, grade 1.

carcinoma," and in a series of 166 rectal carcinomas he found five primary mucoid carcinomas and thirty-six which showed mucoid degeneration. In our series we found only eight mucoid carcinomas, and all were graded either 3 or 4. We found mucoid degeneration frequently in the lower grade lesions. Raiford's¹³ table shows the results of treatment of forty-one patients;

13. Raiford, T. S.: Mucoid Carcinoma of the Gastro-Intestinal Tract: So-Called Colloid Cancer, Surg., Gynec. & Obst. 55: 409-417 (Oct.) 1932.

18 per cent (of eleven patients who had primary mucoid carcinomas) were alive at the end of five years, and 56 per cent of those who had adenocarcinomas and mucoid degeneration were living five years after treatment. He stated that the degree of the formation of mucus is inversely proportional to the grade of malignancy.

Fig. 6.—Section of a carcinoma which has extended just to the fascia propria of the rectum (hematoxylin and eosin stain; slightly reduced from a photomicrograph with a magnification of 15 diameters).

nancy. This view is supported by Ochsenschirt,¹⁴ who studied 188 carcinomas in which the secretion of mucus was prominent. Rankin and Olson¹⁵ found forty-four cases of colloid carcinoma in a series of 453 cases of carcinoma of the colon. They believed that the prognostic difference between colloid and other carcinomas is not great but that colloid carcinomas are likely to present a more serious problem. They did not divide their cases into those involving mucoid carcinomas and those involving carcinomas with mucoid degeneration.

DISTRIBUTION ACCORDING TO CLASS

In this series of 432 resected specimens, 116, or 26.85 per cent, were classed as A, 121, or 28 per cent, as B, and 195, or 45.15 per cent, as C (table 4). Dukes,¹¹

TABLE 5.—Percental Distribution According to Class of Malignancy (Lockhart-Mummery and Dukes)—Comparison of the Results in Five Investigations

Series	Total Patients	Per Cent		
		Class A	Class B	Class C
Broders, Bule and Laird.....	354	28.5	28.2	43.2
Dukes.....	142	21.0	35.2	43.0
Lockhart-Mummery.....	354	30.0	42.3	27.7
Wood and Wilkie.....	59	22.0	42.3	35.6
Gabriel, Dukes and Bussey.....	87	27.6	40.2	32.2

reporting a long series of cases of carcinoma of the rectum in which the lesions had been accepted by surgeons as being operable, gave the distribution as follows: class A, 15 per cent; class B, 35 per cent, and class C, 50 per cent. However, in a series of 142 patients who survived operation, the percental distribution approximates that in this series. This is shown in table 5, which includes the record of other investigators who have used the Dukes classification. In this table is also shown the percental distribution among 354

cases of our series which were selected so as to be comparable with the other series in this table.

The percental distribution according to class is a measure of the type of lesion that the surgeon usually removes at operation, and the lesion is therefore one that is considered operable. It is evident in Lockhart-Mummery's⁴ series that he has recently accepted a greater proportion of class C lesions as operable.

TABLE 6.—Operative Mortality and Three Year and Five Year Survival Rates According to Grade of Malignancy (Broders)—426 Traced Patients Out of 432 Operated On

Grade	Patients Operated On	Patients Traced	Operative Mortality,* per Cent	Percentage of	
				Patients Alive After 3 Years	Patients Alive After 5 Years
1	73	73	7.0	85.0	65.7
2	241	237	16.6	48.9	31.0
3	100	98	22.2	35.7	22.4
4	18	18	28.0	16.6	11.1

* All patients who died within a month in the hospital are included in the operative mortality.

When the distribution of "class" and "grade" are compared (fig. 7), it is found that in grade 1 lesions the proportion of class A to class C growths is approximately 3:1; in grade 2, 1:2; in grade 3, 1:5; and in grade 4 the proportion would be greater than 1:10 if those cases in which metastasis is present were included. Because only those grade 4 lesions in which prognosis was extremely favorable for the patients were operated on in 1929 and 1930, the proportion of class A to class C lesions was smaller.

We compared the percentages of five year survivals of patients whose lesions were in classes A, B and C as reported in four other investigations and ours (table 1). Our calculations in this instance were based on the 354 cases which were comparable to those in the other series. The percentages of five year survivals of patients in each class do not coincide exactly, but the figures are in close enough agreement for their differ-

Fig. 7.—Four hundred and twenty-six traced patients whose lesions have been graded and classed, showing the relationship of distribution, grade, class and five year results. The numbers in the black columns indicate patients (per cent) alive at the end of five years for each class and grade of lesion, calculated from the number of traced patients with each class and grade of lesion who underwent resection. The height of the shaded columns indicates the number of patients who underwent some form of surgical excision and who have been traced.

ence to be explained by the variation in the type of operation done.

Operative mortality is four times as great among patients who have grade 4 lesions as among those who have grade 1 tumors (table 6), and the chance of surviving five years after operation for a patient who has

14. Ochsenschirt, N. C.: The Significance of Mucus-Forming Cells in Carcinoma of the Large Intestine and Rectum, Surg., Gynec. & Obst. 47: 32-35 (July) 1928.

15. Rankin, F. W., and Olson, P. F.: The Hopeful Prognosis in Cases of Carcinoma of the Colon, Surg., Gynec. & Obst. 56: 366-374 (Feb.) 1933.

a grade 4 lesion is 11 per cent, about a sixth of that for patients who have grade 1 lesions. These facts lend justification to the conservatism of those surgeons who observe caution and often refuse to operate on patients who have grade 4 carcinomas.

The operative mortality of patients who have class C lesions is almost twice that of patients whose lesions are in class A, whereas the chance of surviving five years for a patient who has a class C lesion is a fifth as great as in one who has a class A lesion (table 4). If the percentage of five year survival of patients is calculated, the rate for those who have class A lesions is 69.6 per cent, for those who have class B lesions 32.2 per cent and for those who have class C lesions 14.6 per cent. On the same basis, the five year survival rate for patients who have grade 1 lesions is 65.7 per cent, for those who have grade 2 lesions 31.6 per cent, for those who have grade 3 lesions 22.4 per cent, and for those who have grade 4 lesions 11.1 per cent (table 6).

The relationship of grading and class to the five year survival rate has been discussed. Figure 7 shows the distribution and the relationship of grade and class to the five year survival rate. In this figure an actual and relative decrease in the number of patients who are alive five years after operation is shown as the grade increased from 1 to 4 and as the growth advanced from A to C in each grade. The advantage of combining the two classifications in relationship to the number of patients alive five years after resection is clear. In each grade the ratios of five year cures are approximately three, two and one with respect to class A, B and C. For example, 65.7 per cent of all patients who have a grade 1 carcinoma and who survive operation are alive five years after resection (table 6). In grade 1 cancers the chance that the resected specimen is in class A is three times that of its being in class C. According to whether the growth removed is in class A, B or C of grade 1, the chances for survival of the patient five years after operation are, respectively, 77 per cent, 60 per cent and 33 per cent (fig. 7).

On the basis of our studies, it can be said that 22.4 per cent of all patients who survive resection of a grade 3 carcinoma will be alive five years after operation (table 6). There is a 65 per cent chance that a grade 3 tumor will be in class C, in which patients who have such a lesion have a five year survival rate of 11 per cent. There is a 21 per cent chance that the lesion will be in class B, in which patients having such a lesion have a 24 per cent chance of a five year cure, and there is a 12 per cent chance that the lesion will be in class A, in which patients have an 83 per cent chance of living five years or longer (fig. 7).

As the grade increases from 1 to 4 there is a proportionately lessened chance that the patient will be alive five years after operation, and patients who have class A lesions in each grade except grade 4 have a better chance of being alive five years after operation.

We wished to determine whether or not carcinomas of high grade grew faster and caused death more quickly than those of lower grades. The average duration of life was therefore calculated for patients, according to lesions in each grade, who had survived operation for less than five years. The average duration of life of such patients who had grade 1 carcinomas was 29.5 months; grade 2, 26.5 months; grade 3, 25 months, and grade 4, 20 months. On the basis of such evidence it would appear that the rate of growth or at least the speed with which metastases terminate life is directly proportionate to the grade of malignancy.

SUMMARY AND CONCLUSIONS

Four hundred and thirty-two resected specimens of carcinoma of the rectum were graded according to the Broders¹² method and also grouped according to the Dukes method of classification. The distributions of grade and class were studied in comparison with other investigations and also in relationship to survival after operation. On the basis of the entire study, certain conclusions were reached:

1. The presence or absence of mucus loses importance as a guide to prognosis if histologic grading is done by the Broders method.

2. Tumors of higher grades are more rapid in growth and their metastases cause the death of the patient earlier than those of lower grades.

3. The classification of the lesion according to the method of Dukes is also correlated with postoperative life; the higher the class, the less the percental survival.

4. A combination of the Broders grading and the Dukes classification yields a prognosis of survival more accurate than either method taken separately.

EXPERIMENTAL WESTERN EQUINE
ENCEPHALOMYELITISSUCCESSFUL TREATMENT WITH HYPERIMMUNE
RABBIT SERUM

JOSEPH ZICHIS, PH.D.

AND

HOWARD J. SHAUGHNESSY, PH.D.

CHICAGO

There is a general impression that treatment of a disease in which the etiologic agent is a virus is of no value after the infection has become established. Rivers¹ probably presented the opinion of other authorities as well as his own when he wrote the following in 1936: "Such a phenomenon throws light on the clinical observations that the administration of convalescent or immune serum to an individual in whom the signs and symptoms of a virus disease are already manifest is without value." It is of interest that Rivers² has indicated (in the Lane lectures given by him in 1939) that he has modified his point of view to the extent of admitting that measles can be treated after the onset of the typical early signs and symptoms of the disease. However, the majority of clinicians and investigators hold to the view expressed by this authority in 1936. The conception that "once a virus has entered a cell no amount of antiserum brought in contact with the cell can injure the virus or hinder its activity" has resulted from the investigations of several groups of competent workers³ on serum therapy of virus infections of tissue cultures. If this is admitted as a fact,

it seems equally apparent that all cells are not invaded at once in most virus infections at least. From studies of infections in tissue cultures it has also been learned that, if serum is brought into contact with cells before their exposure to virus, infection may be aborted. Therefore, even after the development of early signs and symptoms of a disease, the administration of serum should be of value to the person or animal by penetrating the cells surrounding the parasitized cell and neutralizing any virus which attempts to invade them. The acceptance of these premises suggests that investigation of the effect of serum on the whole organism infected by a disease should give one a better understanding of the potentialities of serum therapy than do studies made on infected cells in tissue cultures.

killed more than one month later. This is compared with the control group in which only one of the five recovered animals showed extensive pulmonary lesions. Practically all the remaining animals in both groups of serum treated mice showed some pulmonary lesions while three of the five survivors in the control group had no lesions at all. Laidlaw and his colleagues made this significant statement: "Here it may be noted that these lesions were convincing evidence that the virus had reached and produced damage in the lungs, and that concentrated serum was powerful enough to arrest the pathological process."

Prevention or modification of measles by convalescent or "normal" serum is so generally accepted that it has become a routine service of physicians in many com-

There are several examples of apparently successful serum therapy of virus diseases in man or experimental animals which deserve to be better known. The first of these was the study of serum therapy of influenza in mice reported in 1935 by Laidlaw, Smith, Andrewes and Dunkin.⁴ They found that concentrated serum obtained from a hyperimmunized horse had "a beneficial action on mice already infected with virus." In their main experiment the fatality in three groups of twenty-five mice each was as follows: controls given no serum, twenty deaths; mice receiving serum twenty-four hours after injection of virus, eight deaths, and mice receiving serum forty-eight hours after injection of virus, ten deaths. Probably their most striking observations were that ten of the seventeen successfully treated mice that received serum twenty-four hours after infection and ten of the fifteen successfully treated mice that received serum forty-eight hours after infection showed extensive lesions of the lungs when

munities. The general opinion has been, however, that serum therapy is of no value after the catarrhal symptoms have appeared. Until very recent years the few studies which had been made were unsuccessful or inconclusive. Most of the patients treated after onset of clinical symptoms received only from 5 to 10 cc. of convalescent serum by the intramuscular or subcutaneous routes, which is about the prophylactic dose. In 1936 Levinson⁵ and in 1939 Levinson and Conner⁶ made an attempt to secure objective evidence of the effect of serum therapy of measles after the appearance of clinical symptoms and Koplik spots but before the eruption. They limited their cases to those in the pre-eruptive stage because of the well known fact that the temperature subsides and symptoms diminish after the appearance of the rash. Their results in the treatment of sixteen patients with measles, fifteen of whom were

hospitalized for other infectious diseases, were striking. Six patients had a normal temperature on the evening of the day the rash appeared, although it is usually stated that the temperature should be highest at about that time. In most of the other cases there was a sharp drop in temperature. The character of the eruption was greatly modified and the alleviation of the other

Fig. 1.—Section of brain of untreated guinea pig; $\times 48$.

signs and symptoms, particularly the cough, was marked. In analyzing the reasons for their success and the failure of previous workers it must be emphasized that Levinson and Conner used from 20 to 50 cc. of convalescent serum and administered it intravenously. These dosages are equivalent to from five to ten times those used by other investigators, and the intravenous route made the serum more available. Kohn, Klein and Schwarz⁷ also reported that from 40 to 50 cc. of convalescent serum given intravenously in the pre-eruptive or early eruptive stages was successful in modifying the disease. They also found that 200 cc. of "normal" human serum was needed to obtain the same results secured with from 40 to 50 cc. of convalescent serum.

Meyer and Eddie⁸ recently reviewed the literature on the treatment of psittacosis by convalescent serum and found that the opinion of most of those who had used it was favorable. They cited a case of their own in which convalescent serum was successfully employed in large dosage and state "The causal relationship between the injection of the serum and the crisis is too apparent to be merely a coincidence." They also observed that convalescent serum is of low potency and that better results should be expected from a hyperimmune serum. While these observations are, of course, not conclusive, they add an impression that another virus disease can be treated successfully with serum if large enough dosages are employed.

While the possibility that man can be infected by the virus of equine encephalomyelitis was pointed out by Meyer⁹ a number of years ago, interest in the human disease was first aroused by the Massachusetts epidemic¹⁰ in 1938. Since that outbreak, which is

believed to have caused about thirty deaths, a number of other cases have been reported. It is quite natural that serum therapy should have been attempted in the treatment of such a highly fatal disease. However, the isolated reports on the few human cases of equine encephalomyelitis treated with serum have been either disappointing or unconvincing. These results are probably not significant in view of the relatively small dosage of serum employed and the lack of knowledge concerning its potency.

The only previous report that we have seen on the use of serum in the treatment of equine encephalomyelitis in experimental animals is that of Wyckoff and Tesar.¹¹ These investigators worked with a commercial unrefined hyperimmune horse serum. Unfortunately no data were presented concerning its potency. Monkeys each receiving 10 cc. of this serum twenty-four and three hours respectively before intranasal instillation of virus were protected. They were not immune when tested by another intranasal instillation of virus seven weeks later, indicating that their immunity had been due to "passive inhibition of infection." Monkeys given 10 cc. of serum at the first appearance of fever and again twenty-four hours later were not benefited in any way. This was true with the use of both Western and Eastern serums. In another series of experiments Wyckoff and Tesar gave 10 cc. of serum intravenously to monkeys three or twenty-four hours after virus was administered intranasally. Three of the six monkeys treated in this manner were protected but were reinfected intranasally seven weeks later, indicating that the protection "had been essentially passive." They concluded that serum "given at the time of first symptoms (fever), or later, has been without beneficial influence upon the course of either Eastern or Western disease."

This is a progress report of our studies on the treatment of Western equine encephalomyelitis with rabbit

Fig. 2 (guinea pig 8, table 2).—Section of brain of guinea pig treated with serum when visibly ill; killed twelve days after treatment; $\times 48$.

hyperimmune serums. It should be emphasized that the potency of rabbit serum prepared in this laboratory was much higher than that of commercial horse serums which we have tested. The protection test used in standardizing our serum is also a more rigorous procedure than the *in vitro* neutralization test commonly employed.

METHODS AND MATERIALS

Virus.—The Western equine encephalomyelitis virus was employed in these studies. The strain used was obtained from Dr. Carl Ten Broeck of the Rockefeller Institute for Medical Research in January 1939 and was labeled "Western E. E. Kelser." In this laboratory the

Fig. 3 (guinea pig 5, table 2).—Section of brain of guinea pig treated with serum when visibly ill; killed twelve days after treatment; slightly reduced from a photomicrograph with a magnification of 200 diameters.

virus has been maintained by serial intracerebral passages in guinea pigs. Since receiving this virus its identity has been established several times by protection tests with a specific immune serum¹² and by cross protection tests with a known Western equine encephalomyelitis virus.¹³

In the treatment experiments guinea pig brain virus was used for the inoculation of all the animals, whereas in the hyperimmunization experiments for the production of immune serum a virus which had been cultivated on the developing chick embryo was used. The dilutions of the guinea pig brain virus were made in heart infusion broth in each case, while the chick embryo virus was diluted with buffered physiologic solution of sodium chloride.

Animals.—Guinea pigs of about 400 Gm. and Swiss mice of about 20 Gm. weight were used in the serum treatment studies. Rabbits, each weighing about 4 Kg., were selected for the production of the hyperimmune serum. Rabbits were selected because it is believed that protective antibodies produced in them are of small molecular dimensions and for this reason are probably able to penetrate to the infected tissues more rapidly.

Production of Hyperimmune Serum.—The virus used for the hyperimmunization of the rabbits was propagated on developing chick embryos. After eleven days of incubation the embryos were inoculated through an opening in the shell with a bacteria free virus. Following inoculation on the chorio-allantoic membrane the eggs were sealed with paraffin and reincubated until the embryo died. As a rule all the embryos were dead within twenty hours after inoculation. The embryos were then removed from the eggs and ground in a tissue mill. The minced tissue was adjusted to a 20 per cent suspension with buffered physiologic solution of sodium chloride, following which the suspension was centrifuged for fifteen minutes at 2,000 revolutions per minute to remove tissue particles. The preparation of this virus was carried out under strict aseptic precautions and only virus that was found to be free of bacterial

contamination was used for hyperimmunization of the rabbits. The minimum lethal dose of the virus was about 10^{-10} for Swiss mice.

Each rabbit was injected subcutaneously with two 3 cc. doses of Western virus chick embryo vaccine treated with formaldehyde. The injections were made seven days apart, and ten days after the last dose each rabbit was injected intravenously with 0.5 cc. of the 20 per cent living virus suspension. Thereafter the animals were injected intravenously on Monday, Wednesday and Friday of each week, the dose being doubled at each injection until the maximum amount of 5 cc. was reached. It was found necessary to follow this schedule of immunization for at least twelve weeks before a serum of high potency could be obtained.

Determination of Potency of Serum.—The protective value of the serum was determined on Swiss mice. The test consisted of injecting each of six mice subcutaneously with 1 cc. of one of the following dilutions of the serum: (1) undiluted, (2) 1:100, (3) 1:500, (4) 1:1,000 and (5) 1:1,200. Twenty-four hours after the inoculation of the serum each mouse was injected intracerebrally with 0.03 cc. of a 1:10,000 dilution (about ten times the minimum lethal dose) of guinea pig brain virus. To demonstrate the virulence of the virus, six normal mice were similarly injected with the same preparation of the virus. The mice were kept in individual cages and were observed for twenty-four days.

In these experiments a lot of rabbit hyperimmune serum was not used unless 1 cc. of a 1:1,000 dilution protected at least two thirds of the mice in the potency test. The serum was not concentrated and did not contain a preservative. Rabbit serum was employed in all experiments excepting experiment 4, in which a commercial horse serum was used.

EXPERIMENTS

EXPERIMENT 1.—Each of fourteen Swiss mice was inoculated intracerebrally with 0.03 cc. of a 1:10,000 dilution of infected guinea pig brain. Each of eight of these received 1 cc. of the serum by the intraperitoneal route forty-eight hours following the inoculation of virus. The remaining six mice were not treated with serum and were employed as the untreated controls.

One treated mouse became sick on the fifth day following the injection of virus and died three days later. Its brain and heart blood were cultured and were found to be free of bacterial contamination. Another mouse did not eat and appeared sick for two days following the serum administration but made a complete recovery. The remaining six treated animals did not show any signs of the infection. All the untreated control mice showed symptoms of the disease on the third day following exposure to the virus and died within eight days. In each case, except in one in which an air contaminant was encountered, the cultures of the specimens of heart blood were negative.

Twenty days after inoculation with the virus the seven mice that were treated with serum were tested for immunity. Each was inoculated intracerebrally with 0.03 cc. of a 10^{-8} dilution (about a hundred times the minimum lethal dose) of Western type chick embryo virus. The dilutions were made in heart

13. Supplied by the United States Bureau of Animal Industry.

infusion broth. All became infected and died, demonstrating that they did not become immunized as a result of the inoculations with virus and serum.

EXPERIMENT 2.—Fourteen Swiss mice were used in this experiment. Each was inoculated intracerebrally with 0.03 cc. of a 1:10,000 dilution of guinea pig brain virus. Eight of the animals were treated with serum when they showed visible signs of sickness; the remaining six were not given serum and constituted the untreated controls. All the mice became visibly sick within three to six days after injection of the virus. The mice that were considered to be visibly ill showed the following signs: slowness of movement, roughened coat, refusal of food, tremors and, in some cases, prostration and partial paralysis. The serum was administered intraperitoneally in 2 cc. doses.

Of the eight treated mice three died and five recovered completely. Of the three animals that died one received one dose of serum, the other two and the third three. Three of the mice

The treatment consisted of inoculating the animals intraperitoneally with 10 cc. doses of the serum. The temperatures of the guinea pigs that were to be treated at the onset of fever were taken twice a day and of the others once a day. It is recognized that excessive handling is distinctly harmful to persons or animals with an infection of the central nervous system. To avoid this possibility temperatures of the animals were not taken after the commencement of serum therapy. The results of this experiment are shown in table 1.

As shown in this table, the four guinea pigs that were treated with serum at the onset of fever recovered after showing only slight evidence of the infection. It was necessary to give each of these animals only one 10 cc. dose of serum. Of the four guinea pigs that were treated when definite signs of illness were observed, three survived and one died. To effect recovery in this group, however, it was necessary to administer from 20 to 40 cc. of the serum to each of the animals. All the untreated control guinea pigs contracted the disease and died.

that recovered were each given two doses of the serum, while each of the remaining two was given three doses. The surviving mice were tested for immunity twenty-four days later by intracerebral inoculation of each with 0.03 cc. of a 1:10,000 dilution of guinea pig brain virus. None of the animals became infected, showing that they had developed an active immunity as a result of having an attack of the disease from which they recovered following treatment with serum.

The control mice all became visibly sick in from three to four days after injection of the virus and died within ten days. Cultures of the heart blood of none of the animals that died in the course of this experiment showed any bacterial contamination.

EXPERIMENT 3.—Twelve guinea pigs were used in this experiment, of which each was inoculated intralingually with 0.4 cc. of a 1:100 dilution (at least a hundred times the minimum lethal dose) of infected guinea pig brain. The animals were divided into the following groups: four were given serum at the onset of the first rise in temperature, four were treated when they showed visible signs of the disease and four were not given serum and were employed as the untreated controls. The guinea pigs were adjudged visibly sick if they showed fever, roughened coats, refusal of food, slowness of movements, ataxia and in some instances partial paralysis.

Cultures were made of the heart blood of each animal that died and in every case they were negative.

The seven surviving guinea pigs were tested for immunity twenty days after exposure to the virus by injecting each intracerebrally with 0.25 cc. of a 1:10,000 dilution (about ten times the minimum lethal dose) of guinea pig virus. All four animals that were treated with serum at the onset of fever and one (guinea pig 5) of the group that was treated after characteristic symptoms were observed contracted the disease and died. The two remaining animals that were treated when visibly sick survived without showing any apparent signs of infection. They appeared to have acquired an active immunity from their exposure to the virus, indicating that infection had occurred.

EXPERIMENT 4.—In this experiment a commercial horse serum, produced by hyperimmunization of horses with chick embryo virus, was used for treatment. This serum, when tested for its protective value by the method described, was found to protect when undiluted serum was used, but only one third of the mice injected with the 1:10 dilution of serum survived. The higher dilutions did not show any protective properties. This serum was of low potency, apparently having only about one thousandth the protective value of our hyperimmune rabbit

serum. Consequently, as would be expected, the results of serum treatment in this experiment were not satisfactory.

Each of sixteen Swiss mice was injected intracerebrally with 0.03 cc. of a 1:10,000 dilution of guinea pig virus. In addition each of seven guinea pigs was injected intralingually with 0.4 cc. of a 1:100 dilution of the same virus. The mice were divided into the following groups: Four were treated with

Fig. 5 (guinea pig 1, table 2).—Section of brain of guinea pig treated with serum when visibly ill; killed twenty-nine days after treatment was instituted; $\times 160$.

serum twenty-four hours and four forty-eight hours after inoculation with the virus, four when visible signs of infection could be observed and four were not treated and were used as controls. Of the guinea pigs five were treated with serum at the time they showed visible signs of the disease and two were used as untreated controls.

The mice that were given 2 cc. of the serum twenty-four hours after exposure to the virus survived without showing any apparent signs of infection. All the mice to which serum was administered forty-eight hours after injection of the virus as well as those which were treated when visibly sick and the untreated controls became infected and died. Each of the treated mice in these two groups received about 5 cc. of the serum. Three of the treated mice lived seven days longer than the controls. However, it is not known whether or not this was due to the protective properties of the serum.

Four of the treated guinea pigs died and one recovered. Each of these animals received about 70 cc. of serum. Of the untreated controls one contracted the disease and died whereas the other did not become infected. The brain and heart blood of each animal that died were cultured and, with the exception of one guinea pig brain in which an air contaminant was encountered, were found to be free of bacterial contamination.

In this experiment, in addition to the serum treatment, dextrose solution was administered subcutaneously to the sick animals. Recently it has been reported that dextrose may be toxic to animals with certain virus infections.¹⁴ Possibly this factor may have influenced the results of this experiment.

EXPERIMENT 5.—Thirty-three guinea pigs were used in this experiment, in which hyperimmune rabbit serum was again used. Each of thirty animals was injected intralingually with 0.4 cc. of a 1:50 dilution of a guinea pig brain virus and each of three was injected intracerebrally with 0.25 cc. of the same virus preparation. The animals that were inoculated intralingually were divided into three groups of ten each. In group 1 the animals were not treated with serum and they were used as controls on the infectivity of the virus, in group 2 treatment with immune serum was started at the onset of fever and in group 3 the animals were given serum when they showed visible signs of the infection. The intracerebrally inoculated guinea pigs were employed to establish the virulence of the virus.

The treatment with immune serum consisted of administering the serum intraperitoneally in 10 cc. doses. In addition, for the purpose of keeping up the body fluids physiologic solution of sodium chloride was given in a few cases by subcutaneous inoculation. In a few instances in which the guinea pigs were very sick, about 5 cc. of serum was injected either intravenously or intracardially in order to make the antibodies available more quickly.

14. Hoyt, Anson; Holden, Margaret, and Rawson, Ruth A.: Decreased Tolerance of Mice to Intraperitoneal Glucose Injections in Certain Neurotropic Virus Infections, *Proc. Soc. Exper. Biol. & Med.* **42**: 332 (Oct.) 1939.

In the control group of animals eight contracted the disease and died, while two did not show any apparent infection. Eight of the guinea pigs in group 2 became infected and two did not. The temperature of these animals was taken in the morning and late in the afternoon, and as soon as a rise was observed 10 cc. of serum was administered. All the guinea pigs had a fever within a period of from three to five days following inoculation. Following serum treatment the condition of each animal was observed closely, and if the animal showed further signs of infection more serum was given. Of the eight guinea pigs treated, two showed complete recovery following the administration of the 10 cc. of serum. It was necessary to give four animals an additional 5 cc. One guinea pig at the onset of fever also showed signs of being visibly sick. It was given 10 cc. of serum but died within twelve hours. The remaining animal was killed while serum was being injected intracardially. Thus, of the eight animals treated, six recovered, one died of the infection and one suffered a traumatic death.

In group 3, nine guinea pigs contracted the disease while one escaped infection. Of the nine infected animals five were treated with serum successfully, one was killed while serum was being injected intravenously, one died before treatment could be instituted and one died after it was treated with 15 cc. of serum. One animal died four days after an intracardial injection of serum and when it had apparently recovered from the disease. On autopsy, it was found to have suffered from a pericardial hemorrhage. The results of treatment in group 3 are shown in table 2.

The three control guinea pigs that were inoculated intracerebrally became infected and died within six days. The cultures of the heart blood and brain of each animal that died in the course of this experiment were free from bacterial contamination.

Thirty-three days after the beginning of the experiment we tested four of the recovered guinea pigs for immunity by inoculating each intracerebrally with 0.25 cc. of a 1:1,000 dilution (about a hundred times the minimum lethal dose) of guinea pig brain virus. Two guinea pigs that recovered after treatment with serum at the onset of fever and two animals that recovered following serum treatment when they were

Fig. 6 (guinea pig 1, table 2).—Section of brain of guinea pig treated with serum when visibly ill; killed twenty-nine days after treatment was instituted; $\times 400$.

visibly sick were subjected to this test. The virulence of the virus was tested by the simultaneous injection of two normal guinea pigs intracerebrally. Of the four animals tested for immunity, one that was treated with serum at the onset of fever contracted typical signs of encephalomyelitis and died. None of the remaining guinea pigs became infected, showing that the disease had progressed sufficiently in these animals to produce active immunity. The intracerebrally inoculated animals became infected and died. The summary of the results

of the experiments in which rabbit hyperimmune serum was used for treatment is shown in table 3.

Histopathologic studies¹⁵ were made of the brains of selected animals to determine whether lesions had been present when serum therapy was instituted and to determine whether repair had taken place in the brain tissues of the serum treated guinea pigs. For this purpose two animals that were treated at the onset of fever were killed twelve days after injection of the serum and two of the same series were killed twenty-eight days after serum treatment. Of the animals that were treated with serum after visible illness, two were killed twelve days after the first injection of serum and one was killed twenty-nine days after serum treatment had been instituted. For comparison, sections were made of the brains of six control animals that did not receive serum and died and of two animals that died following injection of serum. The histopathologic studies are here described.

MICROSCOPIC STUDIES

Untreated Guinea Pigs.—Microscopic sections of brains from the control animals disclosed a diffuse and marked inflammatory and degenerative process. There was a mild focal meningeal infiltration of lymphocytes. In some sections there was massive cellular infiltration extending along the fissures (fig. 1). Perivascular infiltration with monocytes and lymphocytes was variable in degree but almost always present. Some proliferation of adventitia could be detected. There was rather diffuse and widespread degeneration of the neurons, which appeared in varying stages of necrosis. In some sections there was focal neuronal necrosis with a marked interstitial cellular reaction consisting of degenerating polymorphonuclear cells, lymphocytes and also glial cells.

Guinea Pigs Treated at Onset of Fever; Killed Twelve Days Later.—A few focal areas of mild lymphocytic meningeal infiltration were visible. The perivascular infiltration, although definite, was minor in degree, consisting of a few loose lymphocytes to a necklace encirclement one cell layer in thickness. Occasional ghost and pyknotic neuronal cells were present.

Guinea Pigs Treated at Onset of Fever; Killed Twenty-Eight Days Later.—These slides were similar to those of the preceding section with the pathologic changes somewhat less evident.

Guinea Pigs Treated When Visibly Sick; Killed Twelve Days Later (table 2, guinea pigs 5 and 8).—There was marked evidence of inflammatory reaction in these sections. There was focal meningeal infiltration with lymphocytes extending down the fissures. Perivascular infiltration and adventitial and intimal proliferation was quite prominent (fig. 2). Many neuronal cells were mere ghosts. Others showed vacuolization or pyknosis with loss of nuclei and irregular outlines (fig. 3). Neuroglial proliferation was evident.

Guinea Pig Treated When Visibly Sick; Killed Twenty-Nine Days Later (table 2, guinea pig 1).—Sections from this animal showed definite evidence of a subsiding inflammatory and degenerative process. Focal infiltration with old lymphocytes could be found (fig. 4). There was a moderate perivascular infiltration of heavily stained mononuclear cells (fig. 5). Adventitial and intimal proliferation of the arterioles was also present. There was little interstitial lymphocytic infiltration, and no polymorphonuclear cells were seen in any of the sections. Degenerated neurons, some pyknotic, others showing vacuolization or disintegration (fig. 6) and some microglial proliferation, were to be seen.

SUMMARY AND CONCLUSIONS

Western equine encephalomyelitis can be treated with hyperimmune rabbit serum with practically complete success in mice forty-eight hours after injection of virus and in guinea pigs after the appearance of the first sign (fever) of the disease. About two thirds of the animals treated with serum when the infection has progressed to the point at which visible signs of the disease manifest themselves can be saved. The fatality in control animals not receiving treatment is 100 per cent.

Probably a higher percentage of animals could have been treated successfully with serum if the earlier visible signs of infection were more striking. Also because of the impossibility of watching the animals twenty-four hours a day in some cases animals failed to receive serum as soon as visible signs of infection appeared. Owing to these facts, as our protocols show, animals were sometimes treated only after onset of paralysis or even when they were moribund. Most of the animals treated when completely prostrated died.

Proof that specific infection actually existed at the time serum therapy was instituted is supplied by three lines of evidence: The disease continued to progress in some animals, causing death. In other cases the disease progressed for a few hours after serum therapy was begun, and some of the animals appeared to be moribund before recovery began. The histopathologic studies of recovered animals that were killed two and four weeks after recovery demonstrate that widespread damage of the tissues of the central nervous system had occurred but that the inflammatory reaction and destructive changes were receding when the animals were killed. This is confirming evidence that the virus was

proliferating in and damaging the brain, and apparently the serum arrested the progress of the infection. Finally, the fact that some of the survivors among the animals treated after onset of symptoms were immune to a subsequent intracerebral injection of virus, whereas those treated earlier were not, indicates that the infection had proceeded far enough to produce an active immunity.

A commercial serum, produced by immunization of horses, which had a potency only about 0.1 per cent as high as that of our rabbit hyperimmune serum, had no beneficial effect on the course of the infection in animals treated after visible signs of the disease appeared. It also failed to protect mice when administered forty-eight hours after injection of virus but was effective when given twenty-four hours after the injection. It is believed that this experiment serves as a good control. Furthermore, it emphasizes the importance of potency and dosage of therapeutic serums.

It is believed that the reason for the success of these studies is that adequate dosage (in terms of antibodies) was employed. The use of rabbit serum, which is believed to have smaller antibody molecules and which probably penetrated to the infected tissues more rapidly, may also have had a favorable influence on the treatment.

Although the number of animals used in these experiments was relatively small, it is believed that the results are significant because of their consistency and because

15. The Pathology Department, Michael Reese Hospital, Chicago, aided in preparing the slides and photomicrographs and in the interpretation of the histopathologic appearances.

they receive strong support from the histopathologic examination and the results of the immunity tests. Further studies are being conducted at this time.

Evidence has been presented from the literature that other virus diseases have been successfully treated with serum. However, as far as we are aware, this is the first instance in which evidence from controlled studies of the successful treatment of a virus disease which causes its chief damage in the central nervous system has been presented.

VITAMIN DEFICIENCIES IN DIARRHEAL STATES

WILLIAM BENNETT BEAN, M.D.

AND

TOM DOUGLAS SPIES, M.D.

CINCINNATI

In the light of present knowledge of nutrition made available by the recent discovery and clinical trial of synthetic vitamins, it is well to appraise the role of disorders other than malnutrition itself which predispose to or precipitate nutritional deficiency syndromes. We know that most deficiency diseases result from a combination of adverse circumstances rather than from a single one. This is well illustrated in cases of so-called secondary deficiencies which follow organic disease. We have been particularly interested in the vitamin B complex factors and in the disease states which result from an inadequacy or complete absence of these factors.

Many circumstances may operate in preventing a person from receiving an optimal amount of the vitamins which he requires. Not only may his intake be inadequate, but his powers of assimilation and utilization of these substances may be impaired. Thus diseases and disorders of the alimentary tract play an important part in the development of deficiency states. The present paper is concerned with the role of chronic diarrhea in the production of such syndromes as pellagra, beriberi and riboflavin deficiency.

The medical literature contains many case reports of vitamin deficiency syndromes which complicated diseases of the alimentary tract. One of the earliest was reported by Rolph,¹ who noted pellagra in a patient with carcinoma of the stomach. Joyce and Seabrook² were the first to call attention to rectal stricture as a forerunner of pellagra. Turner³ too has reported examples of jejunal and ileac stenosis, amebic dysentery and rectovaginal fistula as other gastrointestinal disorders which might eventuate in pellagra. Barnes⁴ recorded a similar complication of chronic ulcerative colitis. Yang and Hu⁵ described a case of beriberi associated with amebic dysentery, ulcerative colitis and operations

shortcircuiting the alimentary canal. Both Strauss⁶ and Stannus⁷ have given comprehensive reviews of the role played by diseases of the intestine in "conditioning" deficiency disease.

MECHANISMS BY WHICH DIARRHEA MAY LEAD TO DEFICIENCY STATES

1. *Increased Loss of Ingested Vitamins.*—(a) In chronic diarrhea the most important loss of vitamins and other food constituents is the direct result of the rapid transit of ingested materials through the alimentary tract. In a number of our patients who developed pellagra, neuritis or cheilosis as a sequel of chronic diarrhea we found that dyes ingested with the food usually appeared in the stool within four hours, and occasionally in less than one hour. It is obvious that this speeding up of intestinal transport does not permit adequate absorption of the food, even if digestion is normal.

(b) In most disorders of the alimentary tract, however, there is a decrease or even absence of some digestive juices so that proper enzymatic attack on the food does not occur.

2. *Decreased Absorption of Vitamins.*—In addition to these primary obstacles there are frequently organic changes in the intestine which may impede absorption. There is evidence to show that many simple sugars, dextrose, galactose and lactose, are not absorbed normally in deficiency states.⁸ It seems probable that the inflamed, scarred or atrophic bowel in chronic diarrhea absorbs poorly.

3. *Impairment of Possible Vitamin Synthesis in the Intestine.*—A consideration not yet studied in man is the possibility that certain vitamins, or even the enzyme systems in which they occur in the body, are formed in the intestine through the agency of bacterial synthesis. It is known that colon bacilli can synthesize nicotinic acid (Knight). In like manner bacteria can form other vitamins from primitive materials containing carbon, nitrogen, hydrogen and oxygen.⁹ There is evidence that sheep normally synthesize several members of the vitamin B complex from simple food elements in the intestine.¹⁰ It is not too novel to suppose that normal bacterial residents in the alimentary canal may play a role in synthesizing vitamins. Whether this is important or not is speculative. In certain infections, notably those of the dysentery bacteria, it is conceivable that the organisms in the intestine use or destroy a large part of the vitamin content of ingested food and leave an inadequate amount for the needs of the host.

4. *Decreased Phosphorylation of Vitamins.*—Phosphorylation of some of the products of digestion ordinarily takes place in the intestinal canal. It is probable that this function is impaired in any diarrhea of long duration.

5. *Additional Factors Leading to Deficiency States in Chronic Diarrhea.*—Individuals with some forms of diarrhea may have a considerable increase in metabolism owing to the fever associated with infection. The advent of cramping pains, anorexia, nausea and vomit-

ing may put an effective blockade on the very source of supply by reducing the intake of food. Any factor which has previously undermined the nutritional status of an individual will increase his liability to a deficiency syndrome in the event of an outbreak of diarrhea. The relationship of these underlying mechanisms is portrayed in table 1.

ROLE OF THE VITAMIN B COMPLEX IN INTESTINAL FUNCTION

There is much evidence to support the opinion that some of the vitamin B complex factors are important for normal intestinal function in animals. The literature on this problem has been reviewed by Borsook, Dougherty, Gould and Kremers.¹¹ They adduced evidence that many of the chronic digestive complaints in a large series of patients could be relieved by the addition of a dietary supplement containing a high concentration of vitamin B complex factors. Evidence for basic function of thiamine in intestinal motility is not conclusive. In experimental thiamine deficiency, Cowgill¹² observed hypochlorhydria and loss of tone in the gastric musculature. Vorhaus, Williams and Waterman¹³ reported a small series of cases in which constipation was relieved following the administration of large doses of thiamine.

In a study on the effect of an intravenous injection of from 10 to 25 mg. of nicotinic acid, we¹⁴ noted that in four of eight subjects examined under the fluoroscope with barium sulfate in the stomach no change could be demonstrated, but the other four had a definite increase in the depth of the peristaltic concentration rings of the stomach. Two of them had severe cramps associated with generalized increase in gastric tonus, considerable decrease in the size of the stomach, and complete cessation of all gastric movement for a minute. After resumption of gastric activity, the contraction waves rose much higher toward the cardiac end than before the injection and were much deeper than they were prior to the administration of the drug. This observation was extended by Crandall, Chesley, Hansen and Dunbar,¹⁵ who noted hypermotility and irregularity in

the intestinal pattern with areas of atony interrupted by areas indicating spasm in B deficient dogs. They concluded "that the P-P factor (nicotinic acid, nicotinamide or any carboxypyridine derivative capable of replacing these in the diet) is essential to the maintenance of normal gastrointestinal motility and that absence of this factor leads to motor dysfunction of the intestinal tract prior to the appearance of the usually accepted deficiency symptoms." They believed the whole B complex to be more effective than is nicotinic acid alone. Thiamine and riboflavin were inactive under the conditions of their experiment.

Thus it is clear that some elements of the vitamin B complex are of great importance in normal alimentary function. This is again demonstrated in the relief of the diarrhea of endemic pellagra by nicotinic acid. When such a diarrhea is not treated, a pernicious cycle begins. Many other vitamin B complex factors, already poorly supplied by the diet, are lost and diagnostic signs of a deficiency of thiamine or riboflavin may appear. Nicotinic acid usually relieves the diarrhea and with the restoration of normal alimentary function the related deficiencies often clear up if they are not too far advanced.

DIARRHEA IN INFANTS AND CHILDREN

There has been little study of the part played by diarrhea in predisposing infants and children to deficiency diseases. Spies, Walker and Woods¹⁶ have emphasized the frequency of nicotinic acid deficiency in summer diarrhea. Where pellagra is endemic it may be impossible in some cases to determine whether a diarrhea is primarily an infection or a deficiency disease. Diagnostic cutaneous lesions are rare in infants,

In most cases included above there were additional factors predisposing to deficiency disease. Pregnancy, childbirth or lactation occurred in thirty-three, infections (not included above) twenty-eight, operations fifteen, alcoholism seven, pernicious anemia two, and there were many other factors.

* Five of these patients had a colostomy.

but chemical tests and the therapeutic response leave no doubt that a deficiency of nicotinic acid often dominates the picture. As an interesting corollary on the effect of diarrheal states, we have seen pellagra in three nursing infants whose mothers were on a grossly inadequate diet during pregnancy (table 2). When a diarrhea occurred in the mother, the child developed glossitis and diarrhea which cleared up when the baby was put on a formula with a supplement of nicotinic acid.

REPORT OF CASES

Because of the complexity of the relationship between chronic diarrheas and vitamin deficiency diseases, several cases will be presented to illustrate different aspects of the problem:

CASE 1.—Pellagra and riboflavin deficiency in a case of rectal stricture. C. D., a Negro woman aged 34, was relieved of the glossitis and diarrhea of pellagra by treatment with nicotinic acid in the Hillman Hospital in the spring of 1938. This was her first attack and followed the prolonged use of liquid petrolatum several times daily to facilitate the bowel movements impeded by a rectal stricture. There was no change in the diet during the period she was followed. Her food intake was never good either in quality or in quantity. She was followed in the clinic during 1939, and another outbreak was controlled with nicotinic acid (300 mg. a day for several weeks). In February 1940 a colostomy was performed for the stricture. The wound was only partially healed when she was seen on April 24. She had a severe cheilosis. She was observed for a period of two weeks, during which the diarrhea persisted unchecked with from five to ten loose stools a day. She was then given paregoric 5 cc. from two to four times a day for five days. The diarrhea was controlled and within two weeks the mouth lesions healed and her weight increased from 98 (44.5 Kg.) to 107 pounds (48.5 Kg.). The operative wound healed. She failed to return for ten days and the diarrhea recurred in severe form. The cheilosis then reappeared and she developed a painful glossitis. These were relieved by riboflavin and nicotinic acid.

A long period of disordered intestinal function occasioned by a rectal stricture and abuse of liquid petrolatum predisposed this patient to the development of pellagra. She was treated successfully with nicotinic acid, but an operation soon precipitated another attack of the disease. Recovery followed the partial restoration of normal bowel function. Later the development of a chronic diarrhea eventuated in a relapse of the cheilosis. The signs of deficiency disease disappeared after the diarrhea was checked by paregoric. When paregoric was stopped, the diarrhea recurred and the lesions once more reappeared. This sequence demonstrates the role of diarrhea in precipitating deficiency diseases. It also shows that, if diarrhea is the prepotent cause of the deficiency state, cure of the diarrhea may relieve the deficiency without other therapy. In this case colostomy reduced the absorbing area of the bowel and decreased the margin of safety, which was already small owing to the poor diet of the patient.

CASE 2.—Riboflavin deficiency relieved with large oral doses of riboflavin while diarrhea continued. A. L., a Negro aged 54, developed a diarrhea in December 1939, which was still present when he was first examined on May 14, 1940, three weeks after admission to the urologic service of the Hillman Hospital. His diet was very meager and his weight had fallen from 140 (63.5 Kg.) to 90 pounds (41 Kg.) in five months. He had a *granulomatous* lesion of the rectum, which had reduced the function of the sphincter. During January he noted a dermatitis of the elbows and legs, which was, however, healing and almost well by May. Pains in his legs and burning and paresthesia of the skin began in February. One week before he was examined, his eyes began to hurt and sores appeared at the angles of the mouth. The patient exhibited a variety of lesions. The pellagrous skin lesion was healed and showed thickened pigmented areas on the elbows, shins and feet. The eyes were inflamed, the scleras muddy and the conjunctival vessels injected, particularly in the circumcorneal area. Photophobia was moderate. There were marked arcus senilis and irregular corneal opacities within this ring. There was an unsustained horizontal nystagmus. The mouth showed fearful caries, snags and gum retraction. The tongue was coated but not unusually red. At both angles of the mouth there were macerated whitish lesions surrounding a shallow fissure. The

pink color of the buccal mucosa spread out over part of the lip which is normally brown and a new line of demarcation appeared. The lips were mottled and there was some cracking and peeling of the superficial layer. There was pain on pressure over the lower part of the legs and the feet and some hyperesthesia of the hands. The knee jerks were very weak and the ankle jerks absent. The heart was regular and a tic-tac rhythm was present. A rectal stricture and granuloma of the penis completed the picture. He was given riboflavin orally, 5 mg. three times daily, for five days during which the diarrhea was not treated. In spite of the continuation of from six to eight bowel movements a day, the cheilosis healed during this period. The conjunctival injection and photophobia disappeared and the patient stated that he felt much improved. Determination made on the riboflavin content of the blood revealed a change from 0.37 to 0.58 microgram per cubic centimeter of whole blood before and four days after treatment was begun.

In this case it was possible to relieve the lesions by fairly large oral doses of crystalline riboflavin even during a continuous diarrhea. After therapy the riboflavin concentration in the blood showed an increase. It seems clear, however, that much of the material given was wasted. It is probable that smaller parenteral doses would have been satisfactory also. His other deficiencies were relieved by nicotinic acid and thiamine.

CASE 3.—Deficiency in "colitis." J. T. M., a white man aged 35, was nervous and high strung. He had a nondescript array of gastric complaints characterized by burning of the stomach, gas, belching, constipation and headache. His diet was barely adequate because he restricted himself owing to his stomach complaints. In February 1939 he had two attacks of "colitis" characterized by a mucous diarrhea, abdominal cramps, tenesmus and some decrease in appetite. These attacks lasted about ten days each. After the second, he began to develop a sore red tongue and cheilosis. He had insomnia, nervousness and considerable burning of the eyes. All signs and symptoms, except for constipation and vague gastric complaints, had cleared up by the end of March, one month after the diarrhea ceased. There were no recurrences of the oral lesions during the remainder of the year. When seen April 10, 1940, he had no sign of any deficiency disease. For experimental purposes he was given thyroid substance (Armour) 1 grain (0.065 Gm.) daily for two weeks and experienced some subjective improvement. The dose then was increased to 2 grains (0.13 Gm.) daily. Sixteen days later he was experiencing an increase in bowel movements to five or more a day. He developed cheilosis and a sore red tongue. Since this study was complicated by an intercurrent cold, the thyroid was discontinued. The lesions cleared up during the next week.

This case, in which the borderline diet provided a perilous margin of safety, reveals that an acute colitis may be the episode which brings out the latent deficiency state. An attempt to produce a diarrhea was successful, and this was followed by an outbreak of glossitis and cheilosis. Whether thyroid acted to increase the metabolism is uncertain but in some other cases in which this treatment was given there was no relapse.

CASE 4.—Failure of vitamin therapy to relieve the diarrhea of advanced ulcerative colitis. M. T., a Negro woman aged 53, was first observed with signs of pellagra in the spring of 1938. Her initial attack occurred in 1924 and there had been several recurrences. Early in March 1938 she developed a diarrhea which, with a few short intermissions, continued until her death. During the spring and early summer of 1939 she was treated with nicotinic acid from 100 to 200 mg. daily and had complete relief of all her symptoms except the diarrhea, which however decreased in severity. She received no treatment during the next fall and winter while the diarrhea continued, and she had from ten to twenty watery stools daily. She was admitted to the Hillman Hospital March 20, 1940, in an extreme state of dehydration and malnutrition. Her weight had fallen from 152 (69 Kg.) to about 75 pounds (34 Kg.) in eight

months. She had a severe glossitis, stomatitis, dermatitis, peripheral neuritis and cheilosis. Laboratory studies revealed red blood cells of 2.7 million, hemoglobin 4.6 Gm., hematocrit 17 mm., serum protein 4.76 with fibrin 0.21, albumin 1.72 and globulin 2.83 Gm. per hundred cubic centimeters. Large intravenous and oral doses of nicotinic acid, thiamine, riboflavin and vitamin B₆ were effective in relieving the signs of glossitis, stomatitis, neuritis and cheilosis, but the diarrhea persisted. A high caloric, high protein diet was given, and repeated transfusions were of no avail as the patient lapsed into a state of vascular collapse. Adrenal cortex extract was given but was of only temporary value. After nineteen days of exceedingly painstaking treatment the patient died. An autopsy revealed an extensive ulcerative colitis with large areas of sloughing, necrosis and gangrene, especially in the sigmoid and rectum. The liver was fatty. No abnormality was seen in the adrenals. There was an early miliary tuberculosis in the peritoneum.

The clinical evidence of pellagra, beriberi and riboflavin deficiency disappeared following large parenteral doses of nicotinic acid, thiamine, vitamin B₆ and riboflavin. The diarrhea, after a short period of improvement, relapsed into the severe type, which persisted until her death. In every case of pellagra in which nicotinic acid has not relieved diarrhea we have found some organic lesion to account for the failure. Many persons with severe diarrhea, if seen early enough, are restored to normal bowel function by nicotinic acid, as was done in this case for a period of time. It seems probable that in this case the initial diarrhea aggravated the deficiency of nicotinic acid. This in turn may have increased diarrhea further and led to a deficiency of thiamine and riboflavin.

TREATMENT

1. *General Measures.*—Whenever diagnostic evidence of a vitamin deficiency disease appears in a patient with chronic diarrhea, it is imperative to institute emergency measures. It is theoretically sound to eliminate the diarrhea at once, but some patients first must be treated for the deficiency state if it is more critical than the underlying disease. In such instances, concentrates (liver extract and brewers' yeast) and crystalline vitamins may be of great value. As soon as the deficiency is controlled, the diarrhea should be investigated and relieved whenever possible.

Absolute rest in bed, preferably in a hospital providing expert nursing and dietary care, is the first requirement. Sedatives, camphorated tincture of opium (paregoric) or preparations of bismuth may be helpful. A high protein, 4,500 caloric diet including frequent supplements of milk and egg nog should be given. Replacements should be made to compensate for any food lost because of excessive vomiting or diarrhea. Solid food should be taken as soon as it can be tolerated. Attention should be paid to restoration of fluid, electrolytes, protein and all other essential substances of which the body may be depleted. In addition to specific therapy with crystalline vitamins, it is well to give concentrates of yeast or liver extract because they contain as yet unidentified factors in the B complex which may be needed.

2. *Specific Therapy—Nicotinic Acid.*—Parenteral injection of nicotinic acid amide should be given as soon as the diagnosis of pellagra is established or even suspected. This compound does not produce flushing, and large doses (250 mg.) may be given intravenously.¹⁷ We attempt to give the patient 1,000 mg. the first

day, 500 mg. daily for a week, and smaller doses thereafter. Repeated small oral doses (100 mg.) are satisfactory if the diarrhea is not severe. Since the exact requirement varies, it is desirable to use large doses. This regimen usually improves the patient to the point where the diet can be taken and a thorough investigation of the cause of the diarrhea is possible.

THIAMINE

Intravenous injections of thiamine hydrochloride, 50 mg. daily in from two to four doses, control the specific deficiency. Smaller doses, from 10 to 25 mg. daily, will control mild cases. If pain is the chief manifestation, it is usually relieved in a spectacular way. Organic changes respond slowly and it may be necessary to continue therapy for many weeks, but results are not encouraging in advanced cases. Wet beriberi is not frequently encountered in chronic diarrheas. Therapy in such cases should include, in addition to thiamine, all the general measures for relief of congestive failure. Digitalis is of little value. Serum protein should be determined to see whether hypoproteinemia is present. If so, it may be corrected by transfusion of blood or plasma if a high protein diet cannot be taken at once.

RIBOFLAVIN

Parenteral injection of from 2 to 5 mg., or ingestion of twice that amount, will relieve most cases. Because of the relative insolubility of riboflavin, oral therapy is usually advised. Cheilosis is an indolent lesion and responds slowly, usually only after several days (from four to seven) of treatment. It has not been demonstrated that a deficiency in riboflavin is fatal to man, but there is no question that the vitamin is of great value in many cases, even when no lesions are present.

VITAMIN B₆

The occasional response to vitamin B₆ among endemic pellagrins suggests that a deficiency of vitamin B₆ may occur in cases of chronic diarrhea. The dose we have used is from 20 to 50 mg. intravenously.

PANTOTHENIC ACID

The indications and dosage for pantothenic acid have not yet been established for human beings.

OTHER VITAMINS

Treatment of deficiencies in vitamins A, C, E and K follows the principles already outlined.

SUMMARY AND CONCLUSIONS

In an area of endemic pellagra, beriberi and riboflavin deficiency we have encountered 100 individuals who developed such syndromes as a complication of chronic diarrhea. This number constitutes about 10 per cent of the patients with deficiency diseases.

Chronic diarrhea predisposes to the development of deficiency syndromes by causing increased loss and decreased absorption of vitamins. If the diarrhea is relieved even without vitamin therapy, the secondary deficiencies usually improve.

In deficiency diseases which occur as sequels of a chronic diarrhea, parenteral injections of crystalline vitamins are essential in proper treatment but do not take the place of a high protein, high caloric diet. Nicotinic acid amide (from 500 to 1,000 mg. daily), thiamine hydrochloride (from 10 to 50 mg. daily) and riboflavin (from 2 to 10 mg. daily) will relieve specific deficiencies in most cases.

THE CLINICAL VALUE OF VITAMIN K

GARNETT CHENEY, M.D.

SAN FRANCISCO

As vitamin K has only recently been discovered, and synthetic substances with vitamin K activity are at the present time receiving intensive study, our knowledge as to the clinical value of this vitamin is as yet very limited. Although its effect on the hemorrhagic diathesis in chicks on a vitamin K deficient diet has been fairly well worked out, its therapeutic use with patients is largely an unsolved problem. A few disorders with K deficiency are now well recognized; its relationship to a number of others seems probable, and it is possible that it may be of some importance in certain hemorrhagic conditions which have received little or no study up to the present time. Largely on empirical grounds it has been stated that this vitamin is of no value in a number of conditions in which free bleeding may occur.

Clinical studies have been advanced to some extent by the development of certain laboratory tests indirectly indicating vitamin K deficiency. However, when the vitamin first became available commercially the chief source was an alfalfa extract, although putrefactive bacteria were also utilized, and during this time therapy was considerably limited by the instability of the early products and the cost of their production. More recently a number of synthetic compounds with vitamin K activity have been discovered.¹ These are readily produced and are stable and have made possible the rapid advancement in knowledge during the past year because a larger number of cases could be treated.

Of necessity the early reports dealing with vitamin K deficiency and its clinical management resulted in an incomplete understanding concerning the use of the vitamin and caused it to be tried in a great many conditions in which there was absolutely no positive indication for its administration. Its actual clinical value at present may well be presented under four different headings:

1. Those conditions in which its use is positively indicated.
2. Conditions in which it is probably of value, at least in certain cases.
3. Conditions in which it may possibly prove valuable but have as yet been insufficiently studied.
4. Disorders in which it has proved unsuccessful.

DISORDERS DEFINITELY ASSOCIATED WITH VITAMIN K DEFICIENCY AND WHICH ARE BENEFITED BY VITAMIN K THERAPY

Disorders definitely associated with vitamin K deficiency and which are benefited by vitamin K therapy are relatively rare but have been reasonably well defined. They may be divided into two general groups. In the first there is an absence of bile in the intestinal tract and this interferes with the normal absorption of the fat soluble vitamin K. This is most commonly encountered in cases of obstructive jaundice due to stones, cancer, stricture and the like and may also be present in patients with biliary fistulas and long stand-

ing duodenal drainage.² A similar situation may arise in patients with acute and severe hepatitis, such as an acute yellow atrophy of the liver and in yellow fever when no bile reaches the common duct.

The second important type of disorder in which vitamin K deficiency has been clearly recognized is the hemorrhagic disease of the newborn and the tendency of premature infants to bleed. These conditions are associated with prothrombin deficiency and are rapidly alleviated by vitamin K therapy.³

DISORDERS IN WHICH VITAMIN K DEFICIENCY MAY OCCUR BUT THERAPY IS NOT CONSTANTLY EFFICACIOUS

The group of disorders in which vitamin deficiency may occur but in which treatment is not constantly efficacious may be divided into four types. In the first a nutritional deficiency would depend on a complete lack of food or a lack of food containing vitamin K.⁴ Even under such conditions it is difficult to understand how true K deficiency could occur, as this vitamin is known to be manufactured by putrefactive bacteria constantly present in the intestine. On a similar basis, deficiency might occur from an obstruction in the esophagus or at the pyloric end of the stomach. It would be more likely to develop in an obstruction high in the jejunum, as occasionally occurs in malfunctioning gastro-enterostomies, as not only would food be shut off from entering the intestine but the bile would be lost through regurgitation into the stomach. In such a case with high jejunal obstruction, recently observed, the obstruction was complete for eight days but plasma coagulation tests for K deficiency were constantly normal and no hemorrhagic tendency appeared.

A second type of case in which deficiency might occur would be a disturbance in intestinal absorption, such as might take place in severe diarrhea, ulcerative colitis, dysentery, multiple strictures, fistulas and possibly sprue. Such cases have been reported,⁵ but a hemorrhagic diathesis developing under these conditions is distinctly uncommon. I have studied a number of patients of this type without yet encountering any in which K therapy seemed indicated. A case of sprue recently observed is a good example (chart 1). The patient never showed any hemorrhagic tendency or clinical benefit from vitamin K therapy, although his prothrombin time (Quick) was prolonged and was reduced by treatment. The blood and plasma coagulation times remained unaltered.

A third type of case in which deficiency might occur is that in which the liver has been damaged by cirrhosis or chronic hepatitis. Such damage would interfere with the utilization of the vitamin and may in certain instances lead to uncontrollable hemorrhage.⁶ This

situation must be relatively uncommon, as I have encountered it only once in a series of fifty-two cases showing evidence of hepatitis and biliary tract disease. This incidence is similar to that reported by Quick⁷ in 1938. In those unusual instances when free bleeding occurs basically as the result of disturbed liver function

Chart 1.—Effect of vitamin K therapy in a case of nontropical sprue without any bleeding tendency. Prothrombin percentage (Quick) increased but clinical condition and blood and plasma coagulation times unaltered.

it seems unlikely that the administration of vitamin K would be effective even by the parenteral route. Such a lack of effectiveness has already been reported.⁸

A fourth type of patient in which mild K deficiency may be present and in whom it would be important to administer the vitamin is the expectant mother. A series of fifteen cases of pregnant women has already been reported⁹ who have been treated with vitamin K before delivery; and it is implied that their offspring are less likely to bleed after birth when the mothers are so prepared. This work needs further confirmation.

CONDITIONS IN WHICH VITAMIN K DEFICIENCY MAY OCCUR AND THERAPY MAY BE BENEFICIAL BUT WHICH HAVE BEEN INSUFFICIENTLY STUDIED

A number of interesting clinical problems has been encountered which may be grouped under conditions in which vitamin K deficiency may occur and in which treatment may be beneficial but which have been insufficiently studied. The first concerns those cases in which deficient absorption of fat may occur which might interfere with the transportation of the vitamin through the intestinal wall. This might take place on a fat deficiency diet or might be due to disturbances in fat metabolism such as occur in cases of sprue and celiac disease and occasionally in pancreatic disorders. Also the proper absorption of fat and the vitamin might be interfered with in cases of biliary tract disease without common duct obstruction, as has been pointed out by Smith,¹⁰ and a case of gallbladder disease has recently been reported in which such a mechanism could have been responsible for the prolonged plasma coagulation

times which were encountered.¹¹ As certain forms of synthetic vitamin K are water soluble, their absorption would not be affected by a disturbance in fat metabolism, but it has not yet been shown that they naturally occur in a human diet.

A second group of cases which has received no attention in the literature to date is that which includes nephritis, hypertension and uremia, particularly when the late but not uncommon tendency to skin and mucous membrane hemorrhages is present. Three such cases have recently been encountered in which bleeding ceased coincident with vitamin K therapy. The effect of the treatment in one of these cases is shown in chart 2. This patient clinically showed purpura and epistaxis, and plasma coagulation time tests were slightly above normal. Bleeding ceased coincident with parenteral vitamin K therapy and the coagulation times were reduced to less than a normal average. It must be recognized that these results in this small group of cases may be purely coincidence, but they indicate that this type of problem deserves further study.

A most interesting problem is the possibility of reducing the blood and plasma coagulation times of a presumably normal person to a minimum of one or two minutes by the administration of vitamin K orally or parenterally. Six individuals without evidence of any organic disease have recently been studied from this point of view. In four of these the coagulation times of the blood and plasma were significantly reduced. The observations on one young woman with a mild psychoneurosis are shown in chart 3. She received vitamin K by mouth and a reduction in the rate of blood and plasma coagulation took place. Here again, as in the group of patients with renal disorders, the series is altogether too small from which to draw any definite conclusions, but it serves to stimulate further interest in apparently normal patients who may have subclinical K hypovitaminosis.

The observation that patients with definite vitamin K deficiency when successfully treated may show a reduction in their plasma coagulation time to less than the normal average when on adequate therapy and the possibility that the blood and plasma coagulation times

Chart 2.—Effect of vitamin K therapy in a case of malignant hypertension and uremia with purpura and epistaxis. Bleeding ceased and blood and plasma coagulation times reduced. Venous thrombosis developed. Arrows indicate single intramuscular injection of 2 mg. of vitamin K.

of normal patients may be reduced by similar treatment suggest the desirability of studying the effect of administering vitamin K preoperatively to patients in whom postoperative bleeding is to be avoided. Theoretically at least an improvement in the coagulability

of the blood might lessen the tendency to postoperative bleeding, which is particularly disturbing following operations on the eye and on the prostate. This is a field which has not yet been explored.

HEMORRHAGIC CONDITIONS IN WHICH VITAMIN K HAS BEEN SHOWN TO BE INEFFECTIVE

One of the first diseases to be studied in respect to vitamin K deficiency was hemophilia. Although the blood coagulation defect in hemophilia is very similar to experimental vitamin K deficiency in fowls, it is apparently not identical and attempts to improve the blood clotting in hemophiliac patients have met with failure. Recently I have tried repeated injections of the newer synthetic vitamin K preparations without any very encouraging results. Its use in various types of purpura whether primary and thrombocytopenic or secondary to aplastic and myelophthisic anemia or to leukemias and sepsis has proved unavailing. Such an instance is illustrated in chart 4. The patient had aplastic anemia with an almost complete absence of platelets from the blood, and skin and mucous membrane bleeding. Oral and intravenous vitamin K therapy were ineffective. Anaphylactic purpura is like-

Chart 3.—Effect of vitamin K therapy on the normal coagulation times of the blood and plasma of a psychoneurotic patient on an adequate diet. Pronounced reduction occurred on the sixth day.

wise not benefited by vitamin K therapy. This lack of success was to be expected, as these purpuric conditions are not associated with disturbances in the soluble globulin of the blood. The use of vitamin K to control blood loss from the nose, esophageal varices, gastric and duodenal ulcers, the colon, hemorrhoids and the uterus has been without proved success to date.

TESTS FOR VITAMIN K DEFICIENCY

The simplest and most certain evidence of vitamin K deficiency is the presence of hemorrhage in a patient with intense jaundice of the obstructive type and in the newborn infant. While laboratory tests are of confirmatory value, such clinical manifestations are a definite indication for immediate vitamin K therapy.

Tests of so-called prothrombin time as devised by Quick¹² and by Ziffren and his co-workers¹³ have been widely used and show a reduction in the thermolabile globulin of the blood which is associated with vitamin K deficiency. An increase in these globulins occurs coincident with vitamin K therapy. They represent an indirect test for the deficiency and have proved of

inestimable value in determining the rest in the relationship of the of liver disease due to a lack of vitamin K. However, they present certain drawbacks which have tended to limit their usefulness. A technical disadvantage is that an unstable tissue extract must be used for the test and

Chart 4.—Lack of effectiveness of vitamin K therapy in a case of skin and mucous membrane hemorrhages and thrombocytopenic purpura due to aplastic anemia. The bleeding was not controlled and the blood and plasma coagulation times were not reduced. Each arrow indicates an intravenous injection of 2 mg. of vitamin K.

such an extract is not readily available except in large medical centers where trained technicians are constantly performing the tests. A second drawback is the fact that the reduction in so-called prothrombin may indicate a deficiency of vitamin K but is not necessarily indicative of a hemorrhagic tendency. If the little known substances in the blood which tend to retard blood coagulation are also diminished in proportion to those which tend to accelerate coagulation, and there is no disturbance of the balance between the two,

Chart 5.—Dramatic effect of vitamin K therapy in surgical case of obstructive jaundice with massive hemorrhage. Bleeding ceased and the plasma coagulation time was rapidly reduced.

the patient is no more likely to bleed than if the blood contained larger amounts of both these substances. Theoretically at least there is a third drawback in that vascular thrombosis may be produced in a patient with a diminished amount of clot promoting substances but with a normal ratio with the anticoagulation substances. Raising "the prothrombin level" under such conditions.

which are often present in cirrhosis of the liver, might so reduce the blood and plasma coagulation times as to precipitate intravascular clotting. Three patients with extensive venous thromboses have been studied in whom these coagulation times were unusually short. One of these was the patient with hypertension and uremia (chart 2). It is, of course, possible that the thromboses in this patient were coincidental, but it must be noted that they occurred parallel with the shortening of the coagulation times.

The plasma coagulation time which is a modification of Howell's prothrombin time¹⁴ has shown certain advantages. It has been employed in following experimental vitamin K deficiency in chicks and has proved satisfactory in the research laboratory.¹⁴ It is a simple test, requiring but two standard chemical solutions and no unstable tissue extracts. It does not indicate a diminution of thermolabile globulin substance but a loss of balance between the clot retarding substances and the clot promoting substances, which is the real basis for the hemorrhagic defect. It may indicate a tendency toward vascular thrombosis which has already been noted. The test is not affected by platelet deficiency as ordinarily encountered in thrombocytopenic purpura. Normal coagulation times for this test are from two to eight minutes when an optimum amount of calcium is added and from three to fifteen when an excess of calcium is used.

A "serum volume test"¹⁵ has been developed as a simple test to detect vitamin K deficiency. It has not proved serviceable in a small number of cases which I have studied.

THE THERAPEUTIC USE OF VITAMIN K

In those conditions in which vitamin K deficiency is associated with an absence of bile in the intestinal tract, the administration of bile salts alone to the patient may be all that is necessary as they will promote absorption of the vitamin. From 1 to 3 Gm. daily is adequate. It is useless to administer the vitamin in this type of case without the addition of bile salts unless a water soluble form is used. Vitamin K may be administered in a number of ways. Certain foods, notably green vegetables such as cabbage and spinach, are an excellent source, and canned mixed greens may be used in the same manner. A product of proved value¹⁶ is made of the stalks of green grasses¹⁷ and is effective in doses of from twelve to twenty-four tablets daily or from 3 to 6 teaspoons daily.

Medicinal products are of two types. One is an extract of alfalfa and contains the fat soluble natural vitamin. The other represents a group of synthetic products which are more or less effective, the base being naphthoquinone.¹

The choice of a preparation may be important. As far as is known at present, vitamin K from natural sources has no definite advantage over the synthetic products which are of equal potency. Food sources are desirable in that they are cheap, and cerophyl is in the same category. They usually supply an excess of the vitamin when given in usual amounts but no standardization of dosage is available. The alfalfa

extract has been available for some time and is highly effective but is more costly than the synthetic products, which have the advantage of being cheap, well standardized and in certain instances water soluble, which makes some of them suitable for hypodermic injection. Parenteral therapy is more desirable than oral therapy in the treatment of infants, of patients who are vomiting and of patients in whom severe hemorrhage makes rapid control desirable. While this vitamin may be quite effective by mouth in from six to twelve hours, it is more rapidly effective by injection.¹⁴ An average therapeutic dose of natural vitamin K or of 2-methyl-1, 4-naphthoquinone is from 2 to 4 mg. daily two days before and seven days after operation. Therapy must be continued indefinitely in cases in which the cause of the deficiency cannot be relieved.

The success of treatment depends on the accuracy of diagnosis as indicated both by the clinical data and by the laboratory observations. In that group of cases in which K deficiency is known to be present the results of therapy represent an outstanding achievement in recent medical research and, in certain instances of otherwise fatal hemorrhage, may prove life saving. This is well illustrated by the case shown in chart 5. Severe postoperative bleeding was occurring subsequent to an operation on the biliary tract, and the plasma coagulation time was greatly prolonged. The hemorrhage was rapidly controlled by adequate bile salt and vitamin K therapy by mouth. Its effect on prolonged prothrombin times and on the prolonged plasma coagulation times is striking and offers a useful laboratory check on the results of the medication. However, it must be borne in mind that, treating a prolonged prothrombin time is not necessarily important clinically, as it may not indicate that a hemorrhagic tendency is present. Actually, a true, clearcut deficiency of vitamin K is rarely encountered.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. BEAN AND SPIES AND DR. CHENEY

DR. THOMAS T. MACKIE, New York: I agree with Dr. Bean and Dr. Spies with one possible reservation—the implication that the deficiency syndromes occurring in diarrheal states are commonly due to increased loss resulting from intestinal hypermotility. In my experience the rate of forward progress of the barium sulfate-water meal is rarely increased above normal and is frequently slower than normal. The roentgenologic changes demonstrable in the small intestine in deficiency disease have been shown to be associated with delayed absorption of substances such as dextrose and potassium iodide. It is probable that they contribute to progressing deficiency. As the authors have pointed out, it is important to appreciate that a major surgical procedure may precipitate an acute deficiency state. Dr. Cheney's paper is in complete conflict with the current literature on vitamin K. Data published by the Mayo Clinic group, by Quick, by Smith and by other leading authorities on the subject show conclusively that the coagulation time is not a measurement of the vitamin K status. In the presence of a normal coagulation time prothrombin deficiency may already be in the danger zone to such a degree that bleeding may occur and the patient actually die from hemorrhage before the coagulation test demonstrates any deficiency whatever. Determination of the prothrombin time or quantitative estimation of prothrombin constitutes the only direct measurement of vitamin K deficiency available at the present time. It has been amply shown that the function of vitamin K is the maintenance and activation of prothrombin, probably through the action of normal liver. Normal blood of man and animals has a prothrombin content far in excess of the amount needed for normal blood coagulation. This natural "hyperprothrombinemia" appears to be physiologic. No data are available to show that vitamin K

may induce an abnormally high prothrombin level. If the orthodox theory of blood coagulation is correct, intravascular clotting cannot be produced by vitamin K, and hyperprothrombinemia has not been observed in thrombosis. Furthermore the blood clotting test which Dr. Cheney has used is not a measure of a pathologic condition even in the presence of thrombosis.

DR. DONALD T. CHAMBERLIN, Boston: My experience with avitaminosis has been in the dietary management of postoperative cases, particularly those following subtotal gastric resection. Following resection, one finds the beefy, rough, sharp-pointed tongue, usually heavily furred, dry mouth and skin, sometimes diarrhea when feeding is begun on the fourth or fifth postoperative day, and usually irritability and occasionally neuritides, though the latter are rare. Formerly these symptoms were thought to be the result of the procedures or of dehydration or both; however, the early improvement resulting from the use of parenteral vitamin B in the form of crude liver extract, or injectable vitamin B complex, makes the diagnosis of vitamin deficiency in these cases certain. My custom has been to start liver injections or vitamin B complex injections, or both, on the second or third day. I have found that by the eighth or tenth day the clinical signs of vitamin deficiency have largely disappeared, the tongue is flat, clean, pink and moist, the eye is bright and the skin warm and moist. I have not noticed any increase in the healing rate of the wound. The loss of vitamins through the digestive tract in diarrheal states is undoubtedly large but difficult to measure and to evaluate. If the diarrhea is the result of a general change in the entire digestive tract there is a greater loss of the fat-soluble vitamins as well as the water-soluble ones than when the lesion, such as ulcerative colitis, involves only the colon, and the absorptive powers of the small intestine are intact. In general, patients with diarrhea who receive additional vitamins improve in appetite and physical well being; however, except in the case of diarrhea as a symptom of primary vitamin deficiency, other measures must be used to check the diarrhea. In my experience diarrhea as a symptom of primary vitamin deficiency has been rare. The points requiring emphasis in the use of Vitamin K are these: 1. In severe liver damage and in such conditions in which fat metabolism is disturbed, as sprue, the prothrombin level may not be appreciably raised or, if raised, may not stay up. 2. It is of the utmost importance to raise the prothrombin level as high as possible and not be satisfied with levels from 70 to 85 per cent of normal, before contemplated operative procedures are carried out. 3. If the level cannot be raised, bleeding must be expected postoperatively.

DR. MANDREB W. COMFORT, Rochester, Minn.: May I join Dr. Mackie in emphasizing the fact that hypoprothrombinemia occurs in four major conditions: (1) inadequate intake of food containing vitamin K, (2) impairment of absorption referable to lack of bile in the intestine, (3) impairment of absorption caused by deficient absorptive surfaces and (4) hepatic insufficiency preventing the utilization of vitamin K. Hypoprothrombinemia, as well as the resulting tendency toward hemorrhage, has been encountered in a variety of diseases or conditions, including obstructive jaundice, sprue, intestinal obstruction, short-circuiting operations such as gastro-ileostomy which reduce the absorptive surfaces of the small bowel, and hepatic diseases of various types. Hypoprothrombinemia plus the associated hemorrhagic tendency has responded satisfactorily to preparations of vitamin K derived both from alfalfa and from fish meal; it has also responded to the synthetic preparations, which are administered orally and parenterally. Toxic reactions have not occurred. The decrease in the prothrombin clotting time (the laboratory measurement of the degree of hypoprothrombinemia present), as well as the cessation of bleeding, occurs within a few hours. The preparations of vitamin K thus far used have been ineffectual in reducing the prothrombin clotting time and in stopping hemorrhage only in cases of advanced disease of the liver, chiefly cirrhosis. The failures in the early use of vitamin K have largely been eliminated by the prescription of adequate dosage in prophylactic and curative therapy and by the use of preparations to be administered intravenously.

DR. JOHN L. KANTOR, New York: There are two points I should like to make. One is a plea to Dr. Bean and his collaborators to simplify the nomenclature of the dosage of the vitamins. It is confusing to have two or three different kinds

of nomenclature, international units, Sherman units and micrograms, to carry in mind. Now that we have crystalline products available, wouldn't it be a great help to all of us to have the dosage recorded in milligrams? It would simplify administration and make for clarity in the use of these important substances. My second point is directed toward Dr. Cheney. He has apparently not yet encountered a hemorrhage in the case of deficient intestinal absorption. This possibility was already stressed by Dr. Mackie. I should like to call attention to a brief discussion of hemorrhage in the sprue type of defective intestinal absorption published in the May issue of the *Archives of Internal Medicine*. When bleeding does occur it may be very serious indeed. At present it is a great comfort to know that the administration of vitamin K will control the symptoms, not only the massive hemorrhages in the intestinal tract but also those in the skin. A word of caution: If the vitamin K is administered by mouth it is usually in a fat medium which cannot be absorbed; it is therefore important to give it in a water-soluble medium, either by mouth or parenterally, so that it can be absorbed in these cases of deficient fat utilization.

DR. WILLIAM BENNETT BEAN, Cincinnati: In answer to Dr. Mackie's statements about intestinal motility in diarrheal states, in many of our cases there was advanced organic disease of the colon or ileum as seen at postmortem. We have given dyes or glass beads, which occasionally appeared in the stool within an hour but were usually apparent between four and six hours contrary to his experience when using barium. In these cases we found particles of undigested food, so this rapidity of transit through the alimentary canal was a factor leading to vitamin deficiency. Whether that is generally so in cases of uncomplicated diarrheas due to deficiency disease I don't know, but in cases of definite organic disease it was a factor. The indications for vitamin B₁₂ are difficult to predict with certainty. The patients whom we have successfully treated were endemic pellagrins or beriberi patients who had been given large doses of nicotinic acid, thiamine hydrochloride and riboflavin and who, following each of these materials, had an increased feeling of well being and relief of specific symptoms and yet were still not completely well. Their complaints were ataxia, difficulty in walking, muscular weakness, nystagmus, pains in the epigastrium and inability to work. Their diets during the time were grossly deficient. When large doses of vitamin B₁₂ were given, some of the patients got dramatic response but some were not specifically helped. It was impossible to predict which would be helped. It was definite that certain ones were able to get up and walk and had a definite feeling of well being, lost the nystagmus and ataxia and were able to perform muscular movements previously impossible. As far as operations go, when dextrose is given in large amounts to any individual in a borderline state of nutrition it is very likely to precipitate a crisis of deficiency disease, and one method to control experimental therapy is to put the patient to bed and give nothing but dextrose and water by mouth. This may be a factor in several postoperative complications. We have a feeling that there will come a time when physicians will cover such administrations of dextrose with B complex vitamins, as is now done with insulin. Dr. Kantor's question regarding dosage is exceedingly important. It is illogical to talk in terms of units derived from assays of impure materials when we have pure chemical substances which can be weighed. Calculations should be made in terms of grams, milligrams and micrograms.

DR. GARNETT CHENEY, San Francisco: I can best answer most of the points that Dr. Mackie raised that were contrary to what I presented by saying this: First, he seems to be about where we were two years ago when we relied on prothrombin determinations alone for our study of vitamin K deficiencies. Second, I can't help but believe that Dr. Mackie has not studied this disease in clinics for a long period, as we have. That goes over a five year period. As long as he relies on so-called quantitative prothrombin—and nobody knows what that is—determinations on which to base his whole classification of K deficiency, I believe we are not talking on the same level; consequently I can't go into that any further with the time allotted to me. I am familiar with bleeding in sprue. I simply stated that we had not seen it, and I cannot help but feel that a laboratory test such as the prothrombin time, which is notoriously unreliable even in the hands of skilled workers, cannot be accepted

as the final word in determining vitamin K deficiency; and I am familiar with the fact that a number of others agree with that. I was rather hasty with regard to dosage and therapy. It has been our habit to give 2 mg. a day or more. We have given it parenterally. The slides I went over showed the rapid response in vitamin K deficiency and obstructive jaundice to therapy. The patient with gallbladder disease received three injections in twenty-four hours with a reduction in time within a matter of hours which showed clearly on the chart, but I did not have time to emphasize that point. I certainly didn't mean to give the impression that vitamin K was not highly efficacious in the type of case in which it should be given. I think its use represents one of the most important recent advances in medical treatment and I am sorry if I gave any impression to the contrary. I did want to emphasize that I think its use must be limited to definite groups of cases and, as long as we treat and just use a laboratory test such as prothrombin time, we may treat some patients unnecessarily.

THE INFLUENCE OF THE LIVER ON THE UTILIZATION OF VITAMIN K

JESSE L. BOLLMAN, M.D.

HUGH R. BUTT, M.D.

AND

ALBERT M. SNELL, M.D.

ROCHESTER, MINN.

It is now well established that proper administration of vitamin K and related compounds will in most instances prevent or control hemorrhage resulting from a deficiency of prothrombin. It has been reported also that administration of these substances is less effective when the prothrombin deficiency is associated with extensive hepatic damage (Smith, Warner and Brinkhous,¹ Warner,² Butt, Snell and Osterberg,³ Stewart and Rourke,⁴ Pohle and Stewart⁵).

The present study was undertaken to determine any possible correlation between the condition of the liver, the occurrence of a deficiency of prothrombin and the subsequent utilization of vitamin K. Hepatic damage was produced by uniform exposure of rats to a known concentration of carbon tetrachloride. The susceptibility of the liver of these animals to carbon tetrachloride was varied by the use of different dietary levels of carbohydrate, protein and fat. Crude concentrates of alfalfa and 2-methyl-1, 4-naphthoquinone were administered to some of these animals and in all instances failed to increase the level of prothrombin in the circulating blood. A detailed study was made also of the possible causes of these failures. The only common factor found was that extensive hepatic injury was associated with depletion of the level of prothrombin and also with failure of response to vitamin K.

From the Division of Experimental Medicine, the Mayo Foundation (Dr. Bollman), and the Division of Medicine, the Mayo Clinic (Dr. Butt and Dr. Snell).

EXPERIMENTAL PROCEDURE

Male white rats (Wistar strain) weighing approximately 200 Gm. each were fed a basic diet which consisted of 44 parts of lean meat, 44 parts of cracker meal, 8 parts of lard and 4 parts of salt mixture and vitamin supplement. Normal rats take 20 Gm. of this diet daily. The rats used in this experiment were kept in individual cages and the uneaten portion of the food was reweighed each day. The mixed diet was fed in 20 Gm. amounts; carbohydrate diet consisted of 10 Gm. of the mixed diet and 7 Gm. of cracker meal; the protein diet was 10 Gm. of the mixed diet and 10 Gm. of lean meat; the fat diet was 10 Gm. of the mixed diet and 3 Gm. of lard. The amounts thus fed were isocaloric. All animals were given the experimental diet for from five to seven days prior to exposure to carbon tetrachloride.

The rats were placed in a closed chamber and exposed to carbon tetrachloride vapor for thirty minutes three times each week as long as the animals survived. The concentration of carbon tetrachloride vapor was uniformly maintained by vaporizing 1 cc. of carbon tetrachloride in 10 liters of air passed through the chamber each minute. The rats were semiconscious at the end of each exposure but recovered rapidly when returned to their cages in air.

EXPERIMENTAL RESULTS

All of the rats that died as a result of the repeated administration of carbon tetrachloride were found to have massive accumulation of blood in the gastrointestinal tract. Many animals gave evidence of intestinal bleeding several days before death. Tarry stools were noted and in many animals signs of anemia were also present. Blood taken at this time usually showed delayed clotting time and in all cases the prothrombin level was found to be less than 30 per cent of the normal value (Quick⁶). Other animals taken before signs of hemorrhage were evident usually showed normal clotting time of the blood but some reduction of the prothrombin content. No definite time relationship was found between the duration of the carbon tetrachloride regimen and the time of reduction of the prothrombin. Usually the changes were not present until the third week but there were numerous exceptions both earlier and later.

The addition of vitamin K concentrates (from 1,000 to 5,000 Dann units daily) to the diet had no influence on the survival time of the rats that received carbon tetrachloride, nor did the further addition of bile salts to the diet show any influence on the occurrence of hemorrhage. Intramuscular injections of vitamin K concentrates, both in water and in oil, were likewise ineffective, as was the oral and subcutaneous administration of 2 mg. daily of 2-methyl-1, 4-naphthoquinone. Likewise the administration of vitamin K proved ineffective in increasing the prothrombin content of the blood of rats found deficient in prothrombin following continued administration of carbon tetrachloride. When administration of carbon tetrachloride was discontinued to animals found deficient in prothrombin, normal amounts of prothrombin were found in from seven to ten days. No definite acceleration of prothrombin formation was found in similar animals which were given large amounts of vitamin K.

Although gross hemorrhage into the intestine was a prominent feature in the condition found at necropsy,

6. Quick, A. J.: The Clinical Application of the Hippuric Acid and the Prothrombin Tests, *Am. J. Clin. Path.* **10**: 222-233 (March) 1940.

microscopic examination of sections from the intestine did not show any evidence of bleeding from large vessels. Petechial hemorrhages were observed in the capillaries of the mucosa in all animals. In many these were confined to the capillaries of the villi of the jejunum, but in others bleeding from almost all of the mucosal capillaries was observed. In a few animals petechial hemorrhages were also observed throughout the entire gastrointestinal tract including the stomach and colon. The greatest changes were always found in the jejunal portion, however. A typical picture of capillary hemorrhage in a jejunal villus is shown in figure 1. Capillary hemorrhage was also frequently found in other organs to a lesser degree than in the intestine. Listed in order of the magnitude of the bleeding observed microscopically, these organs are the liver, kidney, lung, adrenal and pancreas. A few petechial hemorrhages were found occasionally in the heart and skeletal muscle. Because this pathologic change seemed similar to that reported by Griffith and

Fig. 1.—Typical capillary hemorrhage in a jejunal villus of a rat that died after thirty-four days of the carbon tetrachloride regimen; $\times 100$.

Wade⁷ in young rats on a choline-deficient diet, we added 20 mg. of choline daily to the diet of a series of rats receiving carbon tetrachloride. This addition, however, proved ineffective in preventing or delaying the occurrence of hemorrhage in our rats.

The only organ that showed cellular degeneration other than that immediately associated with hemorrhage at the time of death from bleeding after the carbon tetrachloride regimen was the liver. Extensive necrosis was present in this organ and it was usually difficult to find any liver cells which did not show evidence of degeneration. Usually only a few cells remained that could be recognized as hepatic cells. In the animals that survived the longer times there were accumulations of connective tissue and distortion of the architecture of the liver, which indicated that some regeneration of the previously damaged liver had occurred but that the new liver cells were later killed by subsequent carbon tetrachloride. In the animals studied at the time of death no differences in the extent of degeneration of the liver could be observed which could be ascribed to

the different diets taken by the animals. The survival time and other essential data concerning the rats which died from hemorrhage during the carbon tetrachloride regimen are summarized in table 1. It should be noted that the rats that received the carbohydrate diet survived about 50 per cent longer than the rats on the

TABLE 1.—Carbon Tetrachloride Regimen: Death from Hemorrhage

Fat.....	67	29	21	70	28

other diets, while those that received the fat diet died about 12 per cent earlier than those on the mixed or the protein diet.

Microscopic examination of sections of liver taken from rats at various times during the carbon tetrachloride regimen, but before bleeding had occurred, showed some evidence of the protective effects of the diet. Because of the severity of the regimen all the livers were extensively damaged after the first few days and there were no great outstanding differences in appearance with the different diets used. At the same time intervals the greatest amount of necrosis was usually found in the livers of the fat-fed animals and the least in the carbohydrate-fed animals. In some instances the difference was very marked but in others no choice could be made. However, when a difference was present in comparable animals it was always in favor of the carbohydrate-fed animals showing the least amount of necrosis. Regenerative changes in the liver as indicated by the number and size of the round islands of newly formed liver cells were most marked in the meat-fed animals. In many instances these islands of regenerated liver cells did not show as extensive degenerative changes as were found in the other parts of the same liver or were present in the liver of

comparable rats on other diets. It should also be noted that no correlation could be established between the histologic appearance of the liver and the prothrombin content of the blood except for the fact that there was extensive hepatic degeneration in all the animals studied.

Chemical analysis of the livers taken at different times during the regimen likewise failed to show any correlation between the diet used and the prothrombin deficiency. In all animals the carbon tetrachloride pro-

7. Griffith, W. H., and Wade, N. J.: Choline Metabolism: I. The Occurrence and Prevention of Hemorrhagic Degeneration in Young Rats on a Low Choline Diet, *J. Biol. Chem.* 121: 567-577 (Dec.) 1939.

duced a marked lowering of the glycogen content of the liver, approximately a 90 per cent decrease. No marked changes were produced in the lipid content of the liver; the phospholipids and the choline-containing phospholipids were within normal limits but the neutral fat content of the liver tended to increase with time on the regimen and was usually but not always greater in the fat-fed animals. These changes are indicated in table 2. Figure 2 shows the histologic changes of these same livers.

Because of the extensive necrosis of the liver in the animals that showed a prothrombin deficiency and an increased coagulation time, it was considered that an excess of heparin might be present in the blood.⁸ Neutralization experiments with protamine added to normal blood and to the prothrombin-deficient blood did not nullify the difference in coagulation time between

graded 3 on a basis of 1 to 4, and an occasional pus cell. The serum bilirubin was 4.7 mg. per hundred cubic centimeters with a direct van den Bergh reaction. Roentgenograms of the gall-bladder showed a nonfunctioning organ with stones. The flocculation reaction was positive. Roentgenograms of the chest were negative and roentgenograms of the spine revealed only hypertrophic changes in the lumbosacral joints. The serum protein was 6.5 Gm. per hundred cubic centimeters and the bromsulphalein test of liver function revealed dye retention grade 3. The blood cholesterol was 187 mg. and the cholesterol esters were 93 mg. per hundred cubic centimeters of plasma.

The patient became progressively worse in the hospital, and ascites and edema developed; there was also considerable bleeding from the mouth and the gastrointestinal tract. Death was due to hepatic insufficiency. Necropsy revealed cirrhosis of the liver with ascites.

CASE 2.—A woman aged 38 had had painless jaundice for ten months prior to admission. On examination an orange-yellow discoloration of the skin was noted. The liver and

Fig. 2.—Sections of the livers from rats of table 2. All sections show marked degenerative changes. These sections which are representative of the usual appearances show that less degenerative changes occur in the carbohydrate-fed animals. *a* to *d* inclusive, received carbon tetrachloride twenty-two days each; *e* to *h* inclusive, received carbon tetrachloride thirty-nine days each. Examination of sections at a lower magnification than this indicates a greater number of newly formed islands of liver cells in the animals securing the meat diet; $\times 200$.

the normal and the experimental blood. The intravenous injection of as much as 100 mg. of protamine likewise failed to alter the coagulation time or the prothrombin time of blood drawn at subsequent intervals.

CLINICAL RESULTS

The following two cases represent instances of severe hepatic damage associated with a deficiency of prothrombin. The coagulation defect in these cases likewise failed to respond either to large doses of crude concentrates of alfalfa or to synthetic compounds exhibiting marked antihemorrhagic activity.

CASE 1 (fig. 3).—Without any previous significant history except for chronic alcoholism and the use of cinchophen, painless jaundice developed. On examination the concentration of hemoglobin was found to be 13.3 Gm. per hundred cubic centimeters of blood, with 6,800 leukocytes per cubic millimeter of blood. Urinalysis showed a trace of bile, red blood cells

spleen were enlarged, grade 2. There was no evidence of ascites or collateral circulation. There were a few large purpuric spots on her extremities. Otherwise the results of her physical examination were essentially negative.

Urinalysis revealed albumin grade 1, granular casts, and pus grade 1 on the basis of 1 to 4. The hemoglobin was 11 Gm. per hundred cubic centimeters of blood with 4,430,000 erythrocytes and 5,200 leukocytes per cubic millimeter. Blood smears showed hypochromic macrocytosis. The serum bilirubin was 13.8 mg. per hundred cubic centimeters and the van den Bergh reaction was direct. The sedimentation rate was 117 mm. in one hour. The results of the routine flocculation test and roentgenologic examination of the chest were negative. The prothrombin time was forty-two seconds.

Soon after the patient's admission she had a nosebleed and the prothrombin time was further elevated. Following vitamin K therapy the bleeding ceased and the prothrombin time dropped a little but rose again promptly (fig. 4). It was never reduced to less than thirty-two seconds. During her last three weeks illness in the hospital ascites and edema, as well as frequent nosebleeds and purpuric spots on her thighs, developed. The serum bilirubin rose steadily during the last

8. Dam, Henrik, and Glavind, Johannes: Application of the Tissue Extract Method for the Standardization of Heparin, *Skandinav. Arch. f. Physiol.* 52: 221-224, 1939.

two weeks of life. The patient maintained a good urinary output but finally lapsed into hepatic coma. This responded temporarily to the administration of oxygen, dextrose, thiamine hydrochloride and nicotinic acid. Whenever these substances were withdrawn, she lapsed again into coma. The last four days of her life she was almost constantly comatose and there was a considerable amount of bleeding from the bowel. Pneumonia of the base of the right lung developed about a week before she died. Necropsy revealed advanced cirrhosis of the liver.

COMMENT

It should be noted that in all of these experiments the procedure used produced extensive damage to the liver. The small differences noted in the histologic picture of sections of liver from the animals on different diets were due largely to the severity of the procedure. Much greater differences in hepatic damage and survival are rapidly evident when diets deficient in carbohydrate or protein are used. However, in the experiments reported here all the diets contained slightly more of these substances than is necessary for the basal metabolism of the animal and the amount of carbohydrate, protein or fat added to provide additional caloric intake for the animal's activity. Animals not exposed to carbon tetrachloride lived in normal appearing conditions when these diets were fed.

The failure of certain patients with hepatic disease to respond to vitamin K therapy with an elevation of the prothrombin content of the blood appears to be evidence of grave liver impairment. Many of these patients will be found to have suffered irreparable injury. The same failure of prothrombin response to vitamin K may be produced in animals concomitant

Fig. 3.—Failure of response to concentrate containing vitamin K.

with severe hepatic necrosis. It is encouraging to note that in such animals prompt recovery occurs when the hepatotoxic agent is removed and the liver repair is rapid. Even if administration of the hepatotoxic agent is continued, life may be prolonged by the use of diets rich in carbohydrates.

SUMMARY

Severe hepatic injury is invariably associated with a deficiency of prothrombin in the circulating blood. If the hepatic injury is severe enough, the administration of vitamin K is not effective in correcting this deficiency of prothrombin.

With our experimental procedure, extensive hepatic damage was produced in all animals. Livers from comparable animals that received a basic diet to which had been added carbohydrate, protein or fat showed a marked decrease in glycogen. On microscopic examina-

Fig. 4.—Prothrombin level of a patient with cirrhosis of the liver showing failure to respond to vitamin K (2-methyl-4-amino naphthol hydrochloride) supplied by Parke, Davis & Co.; a water-soluble compound of 2-methyl-1, 4-naphthoquinone supplied by Abbott Laboratories, North Chicago, Ill.

tion, the extent of hepatic necrosis appeared greatest with the fat diet and least with the carbohydrate diet, while regenerative changes were more marked in the protein-fed animals. These changes were small in comparison with the extensive necrosis present and no correlation could be made between the condition of the liver and the amount of prothrombin in the blood. However, the animals that received the carbohydrate diet survived without hemorrhage about 50 per cent longer than did those that received other diets.

The deficiency of prothrombin and the lack of response to vitamin K does not appear to be the result of a deficiency of choline either in the diet or in the injured liver. The heparin content of the blood and its antithrombin activity are not greatly altered by extensive hepatic damage.

The failure of vitamin K to maintain the prothrombin level of the blood and the rapid recovery to normal levels of prothrombin after discontinuation of exposure to the hepatotoxic agent indicate that the liver is of fundamental importance in the formation of prothrombin and in the metabolism of vitamin K.

ABSTRACT OF DISCUSSION

DR. STEPHEN MADDOCK, Boston: This is an important paper from both the scientific and the clinical point of view. We have noted at the Boston City Hospital that there are some patients who will not respond to vitamin K, just like the two of Dr. Snell's that Dr. Bollman quoted. When patients of this sort are discovered the prognosis is bad. In reading the original manuscript of Dr. Bollman and his co-authors I noted that the meat-fed animals showed more marked regenerative changes than those on other diets. The islands of regenerating tissue also manifested less susceptibility to subsequent exposure to carbon tetrachloride. Although this fact has been

pointed out by others (Whipple, Opie, Ravdin) the clinician still firmly believes that an almost exclusively carbohydrate diet is necessary in severe liver damage. It may be that a combination of carbohydrate with protein, such as giving plasma intravenously along with dextrose, would be more useful. The question of the mechanism of this failure of vitamin K to work is also quite important. Is it that the liver is required to do something to the vitamin K intake? Does it furnish some co-factor? Or is it possible that in addition to damaging the liver some other factors come in? I did not see anything about fibrinogen determinations, and the prothrombin times were done by the Quick method, which will be definitely affected by lowered fibrinogen. I imagine the authors determined the fibrinogen and said nothing about it. Another question which comes up is whether or not there is an increase in some anticoagulant in the blood. In the original manuscript they determined whether or not heparin was responsible for this bleeding by giving protamine intravenously to their animals. They found no change, so that heparin can be eliminated, but it is possible that there might be some other anticoagulant which could be responsible for the bleeding.

DR. JONATHAN RHOADS, Philadelphia: We have been able to induce hypoprothrombinemias in Philadelphia with carbon tetrachloride, but we have not had as refined a technic as Dr. Bollman has shown you. We have simply given the material by mouth and it works well. Some years ago, when the question of the source of fibrinogen was being studied at the Mayo Foundation, Dr. Mann made the statement that the fact that a hepatotoxic agent will produce a given change cannot be used as proof that the liver is involved in the change. We were so impressed with the logic of this view that Dr. Richard Warren and I performed total hepatectomy in a number of dogs. The prothrombin level declined progressively in these animals until they died. The fall in the prothrombin level was much more rapid than the concomitant fall in fibrinogen concentration. We have observed several patients with hypoprothrombinemia who have failed to respond to vitamin K. While such patients do not all have a bad prognosis, many of them do. Two of these patients died within thirty-six hours after the prothrombin started to rise, another a little later. Sections of the liver obtained at autopsy showed extensive fibrous changes and only scattered liver cells having a normal appearance. With regard to the effect of diet on liver injury produced by carbon tetrachloride in rats, the results obtained by Dr. Bollman were somewhat at variance with those obtained by Goldschmidt, Vars and Ravdin in 1939, who found that in protecting rats against the effects of one hour of chloroform anesthesia much the best results were obtained with a diet that was high in carbohydrate but also high in protein. I should like to ask Dr. Bollman whether any analyses were made on the meat supplement. In Dr. Ravdin's laboratory, difficulty was encountered in using a supplement of beef heart. The expected results were not forthcoming, and it was found on looking up the analysis of beef heart that it contained a substantial amount of fat and that it was necessary to use a pure protein such as casein for the protein supplement.

DR. JESSE L. BOLLMAN, Rochester, Minn.: Dr. Maddock called attention to some things I forgot. He asked about fibrinogen determination. We did determine fibrinogen in our rats. I did not say anything about these determinations because our results were extremely variable. However, in using the Quick method for prothrombin I found it to be accurate in that I can add normal blood, which contains a normal amount of fibrinogen, and also a normal amount of prothrombin to bloods of low prothrombin content. I have diluted this blood; then adding the amount of diluted blood I can determine to a matter of 1 or 2 per cent. I am sure, the actual prothrombin content by the Quick method. Dr. Rhoads brought the difference between my results and the results of Ravdin and his associates. I believe that Dr. Rhoads will agree that changes in the liver, histologic changes in the liver that I showed you, are not of outstanding difference in those different animals. It is pretty much a matter of opinion. Also, considering the fact that Dr. Ravdin's experiments were acute experiments following the administration of one dose of

chloroform, and I used carbon tetrachloride repeatedly. I am not surprised that we can get from a histologic standpoint a variation of opinion. With reference to the utilization of protein, we used muscle for our protein. We also have another series in which I have used casein and another series gelatin, and there is no essential difference among the three.

EPIDEMIC CEREBROSPINAL MENINGITIS (MENINGOCOCCIC)

THE TREATMENT OF 113 PATIENTS WITH ANTIMENINGOCOCCUS SERUM, MENINGOCOCCUS ANTITOXIN AND SULFANILAMIDE

KALEI K. GREGORY, M.D.

EDWARD J. WEST, M.D.

AND

RAYMOND E. STEVENS, M.D.

Assistant Superintendents and Resident Physicians,

Charles V. Chapin Hospital

PROVIDENCE, R. I.

One hundred and thirteen cases of epidemic cerebrospinal meningitis, representing for the greater part a small epidemic of the disease in Rhode Island, have been admitted to the Charles V. Chapin Hospital since February 1935. The epidemic gave us an opportunity to study the method of treatment of the "genus epidemicus" type of the disease and also to determine the relative therapeutic value of the antimeningococcus serum, the meningococcus antitoxin of Ferry and sulfanilamide.

ANTIMENINGOCOCCUS SERUM

A routine method of treatment, similar to the one which had been used successfully at the Herman Kiefer Hospital by Gordon¹ during the 1927 to 1931 epidemic in Detroit, was adopted at the beginning of the epidemic when severe and fulminating cases were encountered. This consisted of alternate lumbar and cisternal

TABLE 1.—Comparison of Case Fatality Rates in Two Groups of Cases Treated with Antiserum and Antitoxin

	No. of Cases	No. of Deaths	Fatality Rate of All Deaths	Within 48 Hours		Excluding Deaths Within 48 Hours
				Deaths	Rate	
Antiserum	43	18	41.8%	7	28.5%	30.6%
Antitoxin	33	14	42.4%	8	57.1%	21.0%
Totals	76	32	42.1%	15	46.9%	27.5%

injections of antimeningococcus serum at intervals of twelve hours during the first thirty-six or forty-eight hours. After this period treatment was administered once daily, preferably by the lumbar route. The doses for intrathecal treatment were from 5 to 10 cc. less than the amount of spinal fluid removed.

Immediately after the initial intraspinal injection and after a satisfactory sensitivity test for horse serum, a large dose of the antiserum (from 30 to 60 cc. for infants and young children and 90 to 120 cc. for older children and adults), diluted two or three times by volume in physiologic solution of sodium chloride containing 5 or 10 per cent dextrose, was given intravenously. These doses given once or twice were ordinarily sufficient but, in very severe cases and those showing persistent septicemia, larger amounts of the antiserum were given several times, preferably during

1. Gordon, J. E.: Medical Report of the Herman Kiefer Hospital for the Five Years 1927-1931, Detroit, Department of Health, Division of Epidemiology.

the first twenty-four hours. Intrathecal treatment was continued until two consecutive negative spinal cultures were obtained.

The first eight of the 113 patients were treated entirely with antimeningococcus serum of several standard brands. Five of these died, a case fatality rate of 62.5 per cent.

ANTIMENINGOCOCCUS SERUM AND MENINGOCOCCUS ANTITOXIN

About this time (March 23, 1935) Hoyne² reported 296 cases of epidemic cerebrospinal meningitis from the contagious disease department of the Cook County Hospital, Chicago. Eighty-five of these were treated

TABLE 2.—Cases and Deaths by Ten Year Age Groups

Age Group	Cases	Deaths	Fatality Rate
1 to 10.....	35	10	28.6%
11 to 20.....	16	10	62.5%
21 to 30.....	10	5	50.0%
31 to 40.....	9	3	33.3%

51 to 60.....	1	0	0.0%
61 to 70.....	2	2	100.0%

with the meningococcus antitoxin of Ferry³ and the remainder, or 211 cases, with two well known standard brands of antimeningococcus serum. The fatality rate in the antitoxin-treated cases was 23.5 per cent compared with 45.9 per cent for antiserum-treated cases.

Early in the same year Banks⁴ in England also reported twenty-five cases treated with the Ferry antitoxin with seven deaths, a case fatality rate of 28 per cent.

Inspired by these favorable reports, we decided to use the new meningococcus antitoxin. The plan was to give meningococcus antitoxin or antimeningococcus serum to alternate patients admitted without regard to the severity of the disease or to the age or sex of the patient. The method of treatment and dosages were the same as those already outlined for antiserum. Seventy-six patients were treated in this way, forty-three with antiserum and thirty-three with antitoxin. The difference in the numbers of cases treated is explained by the fact that patients transferred from general hospitals, where antiserum had already been given, were continued on antiserum, usually of the same make as that previously used.

RESULTS

Eighteen of the forty-three patients treated with antimeningococcus serum died, a case fatality rate of 41.8 per cent. Of the thirty-three meningococcus antitoxin-treated patients fourteen died, a case fatality rate of 42.4 per cent. If patients who died within forty-eight hours of admission are considered insufficiently treated, the rate is 30.6 per cent for the antiserum and 24.0 per cent for the antitoxin.

It is apparent from a comparison of the percentage mortality rates in table 1 that meningococcus antitoxin was no more beneficial than an effective brand of antimeningococcus serum in the treatment of epidemic cerebrospinal meningitis. However, judging from the percentage of deaths occurring within forty-eight hours, it appears that the cases treated with antitoxin were, on the whole, more severe than those treated with the antiserum.

A study of table 2, arranged in ten year groups and respective fatality rates, shows that antiserum and antitoxin were given to equally unfavorable subjects. The youngest patient in these two groups of cases was 3 months and the oldest 64 years old, averaging 14.2 years. The average age of the patients treated with antitoxin was 15.6 years and the average of those treated with antiserum was 13.2 years.

COMPARISON OF OUR RESULTS WITH THOSE OF HOYNE

Our case fatality rate of 41.8 per cent in cases treated with antiserum compares favorably with the 45.9 per cent cited by Hoyne,² but our rate of 42.4 per cent is nearly twice as high as the 23.5 per cent reported by him in his antitoxin-treated cases. The explanation for this difference in results is not obvious. An analysis of factors involved in the therapy of this series of cases fails to reveal any specific reason.

The meningococcus antitoxin used by us was obtained from the same firm⁵ that supplied Hoyne with material for the treatment of his eighty-five cases.

Our method of intrathecal therapy differed from that of Hoyne. We gave alternate lumbar and cisternal injections of the antitoxin every twelve hours during the first thirty-six or forty-eight hours, then followed with one injection daily, by the lumbar route. Hoyne gave lumbar injections once daily, using the cisternal method only when there was a block in the lower route. The fact that our fatality rate among cases treated with antimeningococcus serum compares favorably with that reported by Hoyne seems to indicate that our method of intrathecal treatment was not a factor acting against a favorable rate in the antitoxin-treated cases.

The amount of antitoxin given by us seems to have been adequate. A study of table 3 shows that the average amount of antitoxin administered intrathecally and intravenously in our series of successfully treated cases exceeded that given by Hoyne.

That the answer to this question depends wholly on the therapeutic value of the antitoxin itself may be

TABLE 3.—Amount of Meningococcus Antitoxin Received by Patients Who Recovered in Our and in Hoyne's Series of Cases

	Total Average Amount	Smallest Amount	Largest Amount	Average Amount Parenteral Admin- istered	Average Amount Intrathecal Admin- istered
Our series.....	283.0 cc.	145.0 cc.	620.0 cc.	132.0 cc.	151.0 cc.
Hoyne's series...	161.7 cc.	75.0 cc.	360.0 cc.	59.5 cc.	115.1 cc.

derived from experience in the use of antimeningococcus serum. It is generally known that standard brands of antimeningococcus serum may vary widely in their therapeutic value and that even an effective brand may fail to produce uniformly good results in a given epidemic.

This is likely to be true in epidemics occurring in different parts of the country. It is believed to be due to the difference in the strains of meningococci prevailing in a particular epidemic and the strains used in developing the antibacterial serum. Gordon¹ discarded standard brands of antimeningococcus serum and succeeded in lowering the mortality rate in the 1927 to 1931 epidemic in Detroit by the use, among other measures, of an antiserum developed through immunizing horses with the prevailing strains of the meningo-

coccus. Wright and his colleagues⁶ stated that, when a patient with meningococcic meningitis fails to respond to treatment, one cannot justifiably conclude that the strain of organism encountered is resistant to serum therapy but only that the serum used is not specific for that organism.

Branham⁷ expressed the opinion that various lots of antitoxin undoubtedly vary in efficacy, as do those of antibacterial serum, and this will result in conflicting reports of its value until such time as standardization becomes more satisfactory.

Therefore it seems logical to conclude that our less successful results were due in part or wholly to the difference in action of the meningococcus antitoxin itself.

SULFANILAMIDE

In the spring of 1937, among the many startling reports on the curative power of sulfanilamide, was one by Schwentker and his associates⁸ on ten cases of meningococcic meningitis and one of meningococcemia. Recovery occurred in all but one of the cases of meningitis, indicating the effectiveness of the drug against human infection as well as experimental infection in mice reported earlier by Buttle⁹ and confirmed by Rosenthal and his associates.¹⁰

Encouraged by these reports, we decided to include meningococcic meningitis on our list¹¹ of diseases for treatment with sulfanilamide. The routine method of treatment already described was in no way to be changed except that sulfanilamide would be substituted for antiserum and antitoxin and that intrathecal injections (lumbar) would be given once a day until two negative spinal fluid cultures were obtained.

DOSAGES

The doses of sulfanilamide are summarized in table 4.

The initial dose of sulfanilamide is calculated on the basis of 15 grains (1 Gm.) per 20 pounds (9 Kg.) of body weight up to 100 pounds (45 Kg.). Above this weight it is rarely necessary to exceed a total of 90 grains (6 Gm.). We believe it is important to obtain, as soon as possible, blood and spinal fluid concentration of from 10 to 15 mg. or more of the drug per hundred cubic centimeters and to keep the concentration at this level with adequate maintenance doses. It is better, it seems to us, to err on the side of too large rather than too small doses. We have had patients whose blood and spinal fluid reached a level of 25 mg. of the drug without causing any deleterious effects. Depending on the method of administration, the maintenance dose should be given either every four or eight hours, day and night, during the acute stage of the disease. This procedure is followed until the patient has shown unmistakable signs of improvement. The night doses are then omitted. The daily doses must be continued well into convalescence, usually for from seven to ten days, if relapses are to be avoided.

A check on the level of the drug in the blood should be made from four to eight hours after the large initial

dose to determine whether satisfactory concentration has been reached. If found below the desired level, the next maintenance dose should be doubled, followed in four hours by the regular maintenance dose by mouth. Another determination of the blood level of the drug is advised at the end of twenty-four hours. This is to check on the adequacy of the maintenance doses.

Sulfanilamide is excreted principally through the kidneys. Consequently, to maintain a high and even concentration the fluid intake should be restricted to about 2,000 cc. in twenty-four hours in adults, and proportionate amounts in children.

Sulfanilamide is given in tablets or crushed in water or milk. An equivalent amount of sodium bicarbonate should be given with each dose of sulfanilamide in order to avoid acidosis. This condition is apt to

develop in infants and young children. We have seen it in two of our small children. For parenteral administration, a solution containing 1 per cent of sulfanilamide in physiologic solution of sodium chloride or one-sixth molar sodium lactate is used. When the latter is utilized, sodium bicarbonate is unnecessary.

If the initial dose of the drug is administered by venoclysis, the first maintenance dose by mouth should be given immediately afterward rather than after four hours. This is advisable because of the rapid excretion of the drug by the kidneys as a result of diuresis, which usually follows venoclysis.

METHODS OF SULFANILAMIDE THERAPY

The treatment of epidemic cerebrospinal meningitis has been based principally on the premise that the anti-meningococcus serum, in order to be effective, must come in direct contact with the organisms in the meninges. This necessitated the introduction of the serum directly into the subarachnoid space by way of the lumbar region, cisterna magna or the lateral ventricles.

Since the World War the administration of antibacterial serum intravenously in addition to the intrathecal injection has been generally used on the theory that meningococcemia precedes the meningitis. It has been the belief, however, that little or no antiserum reaches the meninges when given intravenously or subcutaneously.

In 1935 Hoyne² predicted that eventually it would be shown to be entirely unnecessary to administer any

serum intrathecally if sufficient antitoxin was injected intravenously. A year later he¹² reported ninety-six cases treated exclusively by intravenous injections of antitoxin with a fatality rate of 15.9 per cent.

The advent of sulfanilamide has placed this method of treatment of epidemic cerebrospinal meningitis on a more rational basis. Banks¹³ and Willien¹⁴ had reported the cure of meningococcic meningitis with sulfanilamide given by mouth or subcutaneously without intrathecal administration. Marshall and his associates¹⁵ reported that they had found sulfanilamide in all body fluids, including the spinal fluid, when the drug was given by hypodermoclysis as well as by mouth. Allott¹⁶ found that the concentration of the drug in the spinal fluid was very nearly that in the blood. We arrived at the same conclusion after a large number of tests.

These facts, together with the relatively simple technic¹⁷ for determining the concentration of the drug in the spinal fluid and blood, make the intravenous, subcutaneous or oral therapy of meningococcic meningitis entirely feasible. Lumbar puncture is done only for the purpose of diagnosis and drainage. Consequently we changed our original method of sulfanilamide therapy. At first we reduced gradually the number of intrathecal injections and finally omitted all but one injection following the first diagnostic lumbar puncture.

istration or by Levine tube, if necessary, every four hours (day and night) during the acute stage of the disease. In mild cases the administration of sulfanilamide in adequate doses by mouth is sufficient.

RESULTS OF SULFANILAMIDE THERAPY

Since the spring of 1937, twenty-nine cases of epidemic cerebrospinal meningitis have been treated entirely with sulfanilamide. This plan of treatment with sulfanilamide has been continued in spite of the fact that experimental¹⁸ and clinical reports¹⁹ have indicated that the combined use of the drug and antibacterial serum or antitoxin is more effective against meningococcic infection than sulfanilamide alone. Our justification for the continuance of this plan is the fact that our results have been very satisfactory. Also there are clinical reports²⁰ showing good results in the use of sulfanilamide alone in the treatment of meningococcic meningitis.

Five of the twenty-nine patients died, a fatality rate of 17.2 per cent. Four of these were in the group of nineteen patients who received daily intrathecal injections as well as parenteral and oral administrations of the drug, and all these deaths occurred within twelve hours of admission to the hospital. The other death was in the group of eight patients who received but one intrathecal treatment in addition to the parenteral and oral therapy and took place fifty-one hours after

Because of the seriousness of epidemic cerebrospinal meningitis, we consider it imperative that measures to combat this disease be instituted with as little delay as possible. It follows that any method which could quickly bring the concentration of the drug to the optimum level in the blood and spinal fluid should be used. To do this we inject a 1 per cent solution of the drug into the spinal canal at the initial lumbar puncture and immediately follow this with a large dose intravenously or by hypodermoclysis. This helps to raise the blood and spinal fluid level rapidly. It also helps guarantee an adequate concentration against the possibility of poor absorption in the gastrointestinal tract, vomiting or other mishaps which may occur in the management of severely sick and uncooperative patients. When this is accomplished the optimum concentration of the drug is maintained by oral admin-

istration. Two patients who were treated entirely by oral administration of the drug recovered.

Excluding the four deaths within twelve hours, the corrected case fatality rate was 4.0 per cent. This result was impressive. It should be explained that these twenty-nine patients were admitted toward the end of the epidemic when the severity of the disease was decreasing, whereas those treated with antiserum and antitoxin were seen at the peak of the epidemic in 1935 and 1936.

Except for two small children who developed acidosis, there was no serious reaction to sulfanilamide. In no case was the drug discontinued because of its toxic action.

ANALYSIS OF ENTIRE SERIES

There were forty-two deaths in the entire series of 113 cases, a case fatality rate of 37.1 per cent. Exclusion of the twenty-two deaths occurring within forty-eight hours of admission brings the fatality rate down to 21.9 per cent.

The influence of age on the fatality rate in epidemic cerebrospinal meningitis has been generally considered to be most favorable in the group between 6 and 10 years old and very unfavorable under 1 and over 50 years. Analysis of results in table 5 shows the youngest age group to be the most favorable with two deaths in nine cases, a rate of 22.2 per cent. The next favorable group is the 1 to 5 year group, with eight deaths in twenty-eight cases, a rate of 28.5 per cent. The expected favorable age group of 6 to 10 years has a fatality rate of 40.0 per cent.

It is admitted that statistics based on a small number of cases are subject to error and therefore inconclusive. They are presented here primarily for the sake of completeness.

In all but four of the 113 cases, diagnosis of epidemic cerebrospinal meningitis was confirmed by recovery of the organism either from the spinal fluid or from the blood. The four cases in which meningococcus was not found were diagnosed from the clinical observations alone. These were so definite and typical that a diagnosis of meningococcic meningitis was considered justifiable.

COMPLICATIONS AND RELAPSES

There were two complications in the entire series of 113 cases. One was paralysis of the external rectus muscle of one eye, which developed during the acute stage of the disease. The patient was a woman who was treated with meningococcus antitoxin. The other was total deafness in a child 2 years of age who was treated with antimeningococcus serum.

One relapse was encountered in a youth aged 20 years who had been treated with antiserum. He had recovered from the meningitis in five days. Twelve days later he developed meningococcemia. He recovered after a long period of treatment with antiserum, antitoxin, autogenous vaccine and finally sulfanilamide.

SUMMARY

One hundred and thirteen cases of epidemic cerebrospinal meningitis, representing for the greater part a small epidemic, were treated with antimeningococcus serum, meningococcus antitoxin and sulfanilamide. The case fatality rate for the entire series was 37.1 per cent.

A special study comprising seventy-six cases was undertaken to determine the relative therapeutic values of antimeningococcus serum and the meningococcus antitoxin of Ferry. Forty-three cases were treated with antimeningococcus serum and thirty-three with meningococcus antitoxin with a fatality rate of 41.8 per cent and 42.4 per cent respectively. The result in the latter group was not as favorable as that reported by Hoyne. The reason for this is not obvious but appears to be attributable to the inadequate action of the antitoxin itself.

In a group of twenty-nine cases treated with sulfanilamide alone the fatality rate was 17.2 per cent. In the treatment of these cases intrathecal administrations of the drug were reduced to one in each of eight cases and none in two.

Complications were confined to one each of the antiserum and antitoxin-treated cases and none in the sulfanilamide. There was only one relapse and this was in an antiserum-treated case.

These data and our personal experience in the care of patients with epidemic cerebrospinal meningitis during the last five years have led us to draw the following conclusions:

1. The therapy of epidemic cerebrospinal meningitis with antimeningococcus serum and meningococcus antitoxin is, at best, inadequate. The number of deaths is high, irrespective of the amount of serum used and the methods of treatment employed.

2. The meningococcus antitoxin of Ferry has not been impressive clinically. The results obtained with this form of treatment have not been better than those with standard brands of antimeningococcus serum.

3. Sulfanilamide has been shown to be highly efficacious even when used alone. The clinical results are impressive and in some instances dramatic.

4. Sulfanilamide offers the best means by which the treatment of epidemic cerebrospinal meningitis can be simplified. The drug enters the subarachnoid space readily when given intravenously, subcutaneously or orally. This makes intrathecal administrations of the drug more of an expedient than a necessity.

THE DESIVAC PROCESS FOR DRYING
FROM THE FROZEN STATE

EARL W. FLOSDORF, PH.D.

F. J. STOKES, M.A.

AND

STUART MUDD, M.D.

PHILADELPHIA

During the past few years, evidence has been accumulating which supports the value of human blood plasma or serum as substitutes for whole blood transfusion.¹ In the case of traumatic shock without hemorrhage where there is hemoconcentration, plasma may even be preferable to whole blood.² Even when there is no hemoconcentration, the advantage of a blood substitute not requiring matching of type and one readily available immediately in the emergency is clear. The reduction in hemoglobin which patients can endure without danger is extreme; it is reduction in circulating blood volume which must be corrected promptly. In cases of nephrosis and of increased cerebrospinal fluid pressure as resulting from concussion, the advantage of concentrated plasma or serum is added to the other advantages by virtue of an increased osmotic effect to withdraw fluids into the circulatory system. In dry form resulting from desiccation from the frozen state the plasma proteins may be maintained in highly stabilized form, without refrigeration except for long time reserve-storage, and are instantly available for use by dissolving in water to the original or to a more concentrated volume. Although these proteins may be stored either as plasma or as serum, it appears that the former may be preferable by virtue of minimizing the danger of reactions.³

War-time emergency increases the importance of ready availability of large reserves of this agent in the

dry stabilized form. However, the dosage for shock is large, 400 cc. being minimal. The aggregate volume of large numbers of such dosages brings out limitations of previously employed processes of desiccation from the frozen state, e. g. the lyophile⁴ and the cryochem⁵ procedures. Accordingly, we will describe a new process which has particular advantage in processing on the large scale required, the desivac process, which has been on trial in our laboratories for several years.

In the lyophile process the water vapor is removed in vacuum by condensers maintained at the temperature of solid carbon dioxide, -78°C . A pressure well under 0.2 mm. is maintained. In the cryochem process a regenerable chemical desiccant, specially prepared calcium sulfate, is used for removal of water vapor. The pressure can be as high as from 1 to 2 mm.

The difference in critical degree of vacuum of the lyophile and cryochem processes reveals that this factor is a function of the efficiency of the means for removing water vapor. The desiccant in the latter process is more efficient than low temperature condensation, permitting a higher operating pressure. Accordingly, with still more efficient means for removal of water vapor, a yet higher critical pressure might be expected to be possible, permitting direct vacuum pump connection with evaporating frozen material.⁶ To provide properly efficient means of water removal requires that the water be removed from the pump continuously with maintenance of the oil at a low vapor pressure.

We have accomplished this by use of pumps of large volumetric capacity which circulate the oil used in the vacuum seal rather than by ordinary pumps which operate in a static bath of oil. The oil from the exhaust or atmospheric side of the pump is passed continuously through a device for separation of water from oil, a continuously operating centrifuge. The water is separated in liquid phase from the oil-water emulsion and the clarified oil is returned directly to the high vacuum side of the pump. In this way, oil of low vapor pressure is continuously available for the high vacuum seal of the pump, and the water vapor is withdrawn from the high vacuum space, as rapidly as it is evaporated, directly to the atmosphere and is discharged there in the liquid phase. This system is so efficient that it will operate at 4.5 mm. of mercury pressure and still keep the materials frozen solid by loss of the latent heat of evaporation. By the end of the drying cycle the pump finally produces a pressure below 200 microns, which readily removes the last traces of water from the material being desiccated so that the residual moisture content is brought well below 1 per cent.

Degassing and self freezing may be employed⁷ or the materials may be prefrozen before evaporation is started. In the former case only about half as much material may be desiccated with a given size apparatus because a much greater amount of water must be evaporated in order to freeze the material as compared with that necessary merely to maintain the frozen state during desiccation. However, by employing an external cooling means, even if insufficient in itself for freezing, the procedure of degassing and self freezing may be made much more efficient than otherwise and the step of freezing is accomplished most quickly and with less manipulation than by external prefreezing.

The material to be desiccated may be treated in bulk or in the final containers as previously described.⁷ In the latter case the containers may be placed on an external manifold and sealed as previously described.⁸ The metal desitube or can containers appear to have definite advantage for the purposes already described.⁹

The containers may be arranged within a vacuum chamber more conveniently, however, for large scale operation. Because of vacuum insulation, degassing and self freezing operates much more efficiently. When combined with external cooling, operation becomes exceedingly simple.

In order to complete desiccation rapidly, it is desirable to circulate warm water in a jacket in the vacuum chamber to supply the heat of vaporization more rapidly, by increasing the temperature of the radiating source within the metal chamber. Such heating was not necessary in the original methods of Shackell¹⁰ or Craigie¹¹ with glass desiccators and is not necessary when the final containers are on an external manifold.⁷ In the latter case the contents are adjacent to the walls of the containers which are in direct contact with the atmosphere, so that heat input is sufficiently rapid.

For breaking the vacuum at the completion of the process, an arrangement is provided for passing the air to the chamber through the dry-air sterilizer previously described,⁵ except that it is one of larger size and is attached directly to a single large valve. The containers are removed and sealed when on external manifolds of the cryochem apparatus or are placed in desitubes.

The chambers may be designed for sterilization by use of steam at 15 pounds pressure. Also sight-glasses are easily provided for watching the progress of drying, reading thermometers, and the like. Equipment is available for desiccation of from 10 to 100 liters daily in a single apparatus. For these large capacities it is lower in initial cost and operation than either the cryochem or the lyophile apparatus.

Although this process is superior for large scale operation in production of blood substitutes, the cryochem process is preferable for smaller scale operation, as in smaller hospitals, particularly up to 1 liter capacity. The quantities of desiccant required are small and its regeneration is exceedingly simple. We have recently improved the cryochem apparatus so that the desiccant and containers of material to be dried are all within a single chamber. The arrangement of these containers with relation to finally admitting dry sterile air and so on is exactly as described in connection with the desivac process. On regeneration of the desiccant the entire apparatus is sterilized, and the dry-air sterilizer built in the apparatus is reconditioned. During drying, the heat of reaction of the water vapor with the desiccant is utilized as the source of heat for evaporation; this may be supplemented by electrical sources, thermostatically controlled by the temperature of the desiccant.

When it becomes necessary to adsorb ethanol and other organic ingredients from solutions being dried, silica gel may be used. This frequently is an advantage. It also permits external prefreezing by immersing the containers in low temperature baths without concern for the solvent adhering to the outer walls of the con-

6. Except at a higher pressure, the low mass per unit volume of vapor would require use of impracticably large pumps.

ainers. Although in the cryochem process silica gel is only one half as efficient for water vapor as calcium sulfate per equal weight of desiccant, or one fourth per equal volume¹² (based on aqueous tension of desiccants as determined by maintenance of frozen state during desiccation), the two desiccants may be mixed in order to obtain the superior capacity of calcium sulfate for water. Ten pounds of silica gel will adsorb 20 Gm. of ethanol satisfactorily.

SUMMARY

The desivac process, a new process for vacuum desiccation from the frozen state, is more economical than earlier procedures for vacuum drying on the large scale required, for instance in the preservation of human blood plasma for use as a blood substitute. It is entirely mechanical in operation; the water vapor is removed directly from the high vacuum space and is discharged to the atmosphere in the liquid phase. Low temperature condensation or chemical desiccants are not required.

Improvements in the cryochem process for use in smaller laboratories have been made.

Clinical Notes, Suggestions and New Instruments

HYPERTENSION IN A 7 YEAR OLD GIRL WITH WILMS' TUMOR RELIEVED BY NEPHRECTOMY

KARL M. KOONS, M.D., AND MONROE K. RUCH, M.D.
INDIANAPOLIS

The work of Goldblatt,¹ Page² and others has shown that hypertension may be produced experimentally in dogs and monkeys by effecting a relative ischemia of one or both kidneys. There are many ways in which clinical pathology might simulate the experimental methods of these workers. Blatt and Page³ have studied a case of lymphosarcoma with hypertension apparently due to constriction of both renal arteries by the tumor mass.

Ratliff,⁴ Crabtree⁵ and McIntyre⁶ have reported hypertension in patients with unilateral, chronically infected kidney lesions. Of this group Goldblatt has said,⁷ "It becomes probable that the hypertension associated with unilateral or bilateral pyelonephritis in children and adults occurs only in those cases in which there is associated vascular sclerosis or in which the inflammatory disease produces the same effect on renal circulation as does vascular disease." The reported cases of this type which have come to surgery have been uniformly relieved of hypertension.

Recent reviews of the subject of Wilms' tumor, notably those of Priestley and Broders,⁸ and of Bothe,⁹ have made no mention of blood pressure reading.

We wish to present the case of a little girl in whom marked hypertension seems to have been due to unilateral interference with circulation of the kidney by a tumor of the kidney itself.

REPORT OF CASE

C. W., a white girl aged 7 years, entered the Methodist Hospital Feb. 26, 1940, on the service of Dr. Karl M. Koons, with a history of swelling in the upper part of the abdomen, nontender, noted by her mother seven weeks previously. For the past three or four weeks the child had rested after coming home from school instead of playing as had been her previous habit. No other symptoms were elicited.

The past and the family history were irrelevant except for tonsillectomy in June 1939, at which time her blood pressure was recorded as 120 systolic, 70 diastolic.

The child was rather pale, active and alert. She was 49 inches (124.5 cm.) tall and weighed 47 pounds (21.3 Kg.); on examination the temperature was 100 F., the pulse rate 96 and the respiratory rate 20.

The physical abnormalities were confined to the abdomen. There was a visible tumor in the left upper quadrant which on palpation was firm, only slightly irregular, partially movable, extending up under the rib margin, across the midline and 3 or 4 cm. below the umbilicus. There was no tenderness. The first blood pressure reading, recorded February 28, was 180 systolic, 130 diastolic.

Laboratory examinations revealed the following: Specific gravity of the urine was 1.009, with a very faint trace of albumin; it was alkaline and showed no pus or blood. The blood showed: hemoglobin content 12.5 Gm., or 82 per cent, red blood cells numbered 4,070,000, white blood cells 4,650, polymorphonuclears 60 per cent, eosinophils 1 per cent, small lymphocytes 39 per cent. Coagulation and bleeding time six minutes.

February 27 an x-ray examination of the kidney, ureter and bladder and an intravenous pyelogram revealed a tumor of the upper pole of the left kidney, apparently malignant.

Dr. J. H. P. Gauss saw the patient as a consultant, and immediate operation was decided on, the preoperative diagnosis being Wilms' tumor of the left kidney. A discussion of operation versus roentgen therapy is of great interest but is outside the scope of this paper.

The blood pressure February 29 at 9 a. m. was 156 systolic, 126 diastolic and at 9 p. m. 190 systolic, 155 diastolic.

March 1, under avertin with amylene hydrate-ethyl chloride-ether anesthesia, a left paramedian incision was made; the peritoneum was incised laterally, the kidney freed, and the vessels and the ureter clamped, ligated and cut. Enlarged glands extended out from the pelvis of the kidney and along the aorta and vena cava. One nodule was noted in the under surface of the left lobe of the liver, and no effort was made to remove any of the glands. A transfusion of citrated blood had been started during the operation, and the patient was never in shock. Ten minutes after the operation the blood pressure was 135 systolic, 65 diastolic.

The postoperative course was uneventful. The pulse, which before operation had averaged 96, averaged 120 during the remainder of the hospital stay. The temperature came down to normal on the third day and remained constantly so after the sixth day. Blood pressure readings were as follows: March 2, 130 systolic, 80 diastolic; 3d, 125 systolic, 75 diastolic; 4th, 104 systolic, 68 diastolic; 5th, 125 systolic, 85 diastolic; 6th, 120 systolic, 60 diastolic; 8th, 130 systolic, 90 diastolic; 9th, 128 systolic, 68 diastolic; 10th, 120 systolic, 80 diastolic; 11th, 116 systolic, 76 diastolic. The patient was discharged in good condition on the eleventh postoperative day.

ABSTRACT OF PATHOLOGIC REPORT

The specimen consisted of a tumor mass and kidney 15.5 by 10 by 9 cm. There was a small, firmly circumscribed portion apparently of kidney tissue, although on section the architectural markings were not apparent. On section the tumor itself was very soft and yellowish gray, with small areas of hemorrhagic infiltration. There were a few cystlike cavities filled with a yellowish, gelatinous fluid. Microscopically there was seen fairly normal kidney tissue; then as the tumor was approached this blended into a very firm fibrous tissue, finally blending into the tumor itself, which was made up of compactly arranged round cells, irregular as to size, shape and staining qualities. There was no definite architecture; the stroma consisted of fine fibrous connective tissue.

Farther away from the kidney substance there were areas of marked inflammatory reaction with numerous polymorphonuclears and necrotic cellular debris. The pathologic diagnosis was embryoma of the kidney (Wilms' tumor).

COMMENT

The exact mode of interference with renal circulation is not apparent but was probably due to pressure of the tumor tissue invading the renal pedicle and adjacent lymph nodes. The compactness of the tissues in that area was most evident at operation, before the kidney was freed from its bed. Another possibility was that the neoplastic mass which almost entirely surrounded the kidney acted in the same manner as the cellophane envelope used by Page² to produce experimental hypertension.

The hypertension could scarcely have been due to some product of the tumor itself as metastases were found, yet the blood pressure returned to normal level.

CONCLUSION

In the case here presented of a child with marked hypertension apparently due to unilateral interference with renal circulation by Wilms' tumor, the hypertension was relieved by nephrectomy.

A SIMPLE, EFFECTIVE, FABRIC RESTRAINT-SPLINT

MAX KAPLAN, M.D.; S. O. LEVINSON, M.D., AND
PHILIP LEWIN, M.D., CHICAGO

A simple muscular ankle and wrist restraint has been effectively used as a restraint-splint in the care of patients with acute anterior poliomyelitis and may be used to advantage in many other conditions. In addition to its simplicity it is inexpensive, can be made universally available and can be used repeatedly.

Fig. 1.—Combination restraint and bandage splint. A, showing bandage splint made of heavy cloth with two short strips of cloth attached. One strip made into loop and secured with safety pin. Note ties at ends of cloth. B, three restraint and bandage splints in positions. Note rolls under knees and cotton "doughnuts" under heels. Pads for the soles of the feet are not shown. The combination of this bandage and Carrell's Bradford frame and hinged restraint is excellent.

The indication for its use is as a temporary substitute for the generally used plaster and metal splints for the extremities. In mild cases of poliomyelitis in which there is no paralysis or only slight paresis of muscles of the extremities, the restraint-

splint may be used throughout the acute and subacute stages of the disease.

The purpose of the restraint-splint is to immobilize and comfortably restrain the extremities in order to achieve support, protection against fatigue and overstretching of weakened muscles, and neutralization of antagonist muscle-pull, thus preventing deformities and contractures.

Fig. 2.—Restraint and bandage splint applied to the upper extremities maintaining the physiologic position of neutral muscle pull. Note the pillows, the bandage and the wristlets. The inset indicates the relationship of the arm to the patient's body.

The article consists of a double thickness band of unbleached muslin 6 inches in width and approximately 36 inches in length, hemmed along its four edges. Two shorter strips of muslin about 2 inches in width are sewed, approximately 18 inches apart, on the muslin band in its long axis. Each of these "loop-strips" is attached at its middle, thus leaving the ends free to be looped around an extremity, like a wristlet or anklet, and fastened with a safety-pin. Attached to the corners of the large muslin band are streamers of ordinary cloth bias tape approximately 30 inches in length, which are tied to the sides of the bed or around the foot-support (placed to maintain the feet in dorsiflexion), thus stretching the restraint-splint tautly and securing it in place.

The technic of application to the lower extremities is as follows: The patient is placed on his back with a small flat pillow under the lumbar spine and a small "roll" under each knee. A cotton "doughnut" is placed under each heel. Three restraint-splints are placed across the bed, beneath the patient, at the following levels: (1) around the foot support, (2) just above the ankle, (3) just above the knee. Occasionally, one placed at the midhigh level will be found useful and effective. The tape-streamers are then tied securely to the bed under the spring and mattress or about the foot-support, stretching the restraint-splint flat and taut. The "loop-strips" are placed around the extremities at the various levels and fastened snugly, but not tightly, with safety-pins. Those for the feet are placed around the arch and fastened over the dorsum, thus preventing rotation of the foot and leg, and eliminating sand bags and other bulky devices (fig. 1).

The application to the upper extremity is shown in figure 2, in which is also illustrated the ease and convenience with which the restraint-splint is used in conjunction with pillows as supports.

The advantages of the restraint-splint are ease of manufacture, universal availability, low cost, ease of laundering and sterilizing, ease and simplicity of application. Since so little of the skin surface is covered by the loops, a great part of the patient's skin can be bathed and powdered without the restraints being removed. Furthermore, extremities encased in plaster casts or padded aluminum splints during warm weather become hot, sweaty and uncomfortable. These objections are eliminated to

a great extent by this type of splint. The simplicity of removal and application results in a minimum of disturbance and discomfort to the patient during skin care and toilet. In addition, there is no loss or breakage.

COMMENT

The restraint-splint works very well in conjunction with other devices such as the Bradford frame, the Carrell-Girard frame, the Toronto-LeMesurier splints and split mattresses.

The dimensions of the restraint-splint may be varied according to the size of the patient and the anatomic level at which the restraint is to be placed. The distance between the "loop-strips" may be shortened and thus be made to fit any patient by making a fold at the middle of the large band and securing the fold with safety-pins.

The restraint-splints should be laundered well, ironed without starch and autoclaved after being used. They may be stored or carried ready for use by folding and enclosing them in paper, cloth or cellophane wrappers, each one appropriately labeled according to its purpose; viz., "child," "adult," "upper extremity," "lower extremity." Thus they can be made readily available in every hospital, doctor's and health officer's bag.

The entire restraint-splint can be improvised from an old sheet or towel and a ball of twine or some shoe laces and ten safety-pins. It can be used in a respirator, a farm house or an automobile trailer. It can be made economically in large quantities by Red Cross or WPA workers or by any volunteer organization.

This restraint was designed by Misses Blake, Robeson and Black, the supervisors and instructors of pediatric nursing in Michael Reese Hospital, after a careful survey of restraints used elsewhere. It has been used successfully for restraining a child during the administration of parenteral fluids and other medical and surgical procedures. However, the combination and arrangement of several restraints, as herein described, to form what we call the restraint-splint, have not been to our knowledge used or described before.

They may be effectively used in a variety of conditions and situations where temporary or moderate immobilization is necessary: viz., burns, osteomyelitis, fractures, postoperatively and during the transition period following the removal of braces, casts and splints.

The simplicity of the restraint-splint and the relative ease of large quantity manufacture may well render it useful at the battle front during the periods of transportation and temporary care of the wounded. Injured extremities can be rapidly immobilized with this type of restraint-splint, which can be used on a stretcher as well as on a hospital bed.

We should like to call it the Michael Reese restraint-splint, with the notation that it was first used for poliomyelitis patients by Dr. Kaplan.

A PRACTICAL SUBSTITUTE FOR GLASS COVERSIPS

JACK C. NORRIS, M.D., ATLANTA, GA.

My attention has been recently directed to the problem of finding some suitable material that could be used to replace the glass coverslip. Formerly the slips have been imported from Germany, England and Japan. The war has seriously threatened the supply of them, and the price has increased from \$1.50 to \$3.75 an ounce. These factors make the imported slips almost prohibitive to the average hospital laboratory.

After trying various substances, my attention was fortunately directed to plastacele which is made by the E. I. DuPont Company, 626 Schuyler Avenue, Arlington, N. J. Plastacele is perfectly transparent. Regular size coverslips can be easily cut from it with ordinary scissors or any other type of suitable cutting instrument.

Sheets of plastacele can be ordered in various sizes. Ordinarily a sheet measuring 20 by 50 inches will allow about 1,000 coverslips and cost about \$1 a sheet. Order No. C-12-7511.

Coverslips of plastacele are satisfactory for microscopic urinalysis, fecal smears and such purposes. Tissue slides can also be mounted with it, and undoubtedly other uses will be found for them as time passes on.

S10 Doctors Building.

Council on Industrial Health

MEDICAL SERVICE IN INDUSTRY

THE COUNCIL ON INDUSTRIAL HEALTH HAS APPROVED THIS ARTICLE AS ONE OF A SERIES ON MEDICAL SERVICE IN INDUSTRY WHICH WILL APPEAR FROM TIME TO TIME IN THE JOURNAL.

C. M. PETERSON, Secretary.

INTRODUCTION

Large industrial establishments in this country are classified as those which employ more than 500 workers. Many business organizations of this size have found medical supervision over employees, materials, processes and working conditions to be a practical necessity. This trend gains strength as industrialists learn by education and example that maintenance of trained manpower at gainful employment uninterrupted as far as possible by disability from injury or illness is good business. It is possible to demonstrate, as many physicians have done over long periods of time and in all kinds of manufacturing operations, that industrial medical departments can be conducted without compromise of ethical or scientific medical standards

Distribution of Industrial Establishments According to Number of Employees

Establishments Employing	Number of Establishments	Number of Wage Earners
Number of wage earners.....	6,885
1 to 5 wage earners.....	62,164	170,174
6 to 20 wage earners.....	46,402	514,487
21 to 50 wage earners.....	23,138	750,922
51 to 100 wage earners.....	11,911	852,373
101 to 250 wage earners.....	9,745	1,522,670
251 to 500 wage earners.....	3,911	1,363,000
501 to 1,000 wage earners.....	1,660	1,333,323
1,001 to 2,500 wage earners.....	737	1,080,534
2,501 or more wage earners.....	241	1,181,748
Totals	166,794	8,569,231

U. S. Census of Manufacturers, 1937.

and yet in excellent conformity with the purposes of industry. Once this view is widely accepted by industry and the medical profession, greater demand for the services of physicians as a means for conserving the health of workers may be expected.

These demands will probably come soonest from large firms able individually to support adequate medical facilities, yet which have for various reasons failed to develop them. A more important demand should come from small manufacturing units and other commercial enterprises, once a means is found for providing an adequate service which they can with advantage support. The accompanying table describes the distribution of industrial establishments classified according to the number of wage earners employed.

Frequently there is great need for medical service in these small plants, the more so since it is unrealized and since unfavorable sickness or accident experience is not in any sense a function of plant size. The Council on Industrial Health believes that these needs represent a considerable opportunity for medical achievement and that this demand should be encouraged and controlled through the establishment of an educational service which will:

1. Acquaint physicians with the special character of industrial medicine, surgery and hygiene and the necessity for the enforcement of standards defining scope and professional competence.
2. Convince employer and employee alike that medical service in industry merits support only as it is soundly organized economically, scientifically and ethically and that to produce lasting benefits it must be satisfactory both to those who provide and to those who receive the service.

Manufacturers' associations, trade unions, insurance carriers and compensation and other governmental agencies have large and legitimate interests in the workers' safety and health. All are actively engaged in establishing economic, social and humanitarian values of control over industrial accident and disease. In view of this widespread interest the ability of medical organizations to exert a constructive influence on industrial health standards takes on added significance, since other agencies are

not in good position to evaluate medical procedure or facilitate direct application of improved knowledge or technic into actual practice. To relinquish leadership in any program involving the public health to extraprofessional agencies is out of keeping with medical tradition long established in other specialty fields. Principal reliance for improved industrial health standards must rest on medical education and self discipline administered through the physicians' own organizations. The Council on Industrial Health of the American Medical Association was established as a means of focusing attention from all elements in the medical profession on industrial health problems. For identical reasons cooperating committees on industrial health are being organized in the medical societies of states where the nature or concentration of industry appear to justify such a step.

FUNCTIONS OF STATE COMMITTEES ON INDUSTRIAL HEALTH

A program has been developed as a guide to committees on industrial health in state medical associations which has the following well defined objectives:

1. To train industry and labor to the value of industrial health conservation.
2. To develop a clear understanding of the proper scope and functions of industrial medicine and to clarify relationships between private and industrial practice.
3. To keep the medical profession informed about all accepted methods for reducing the frequency and severity of industrially induced disability.
4. To elevate medical relations under workmen's compensation.
5. To scrutinize all legislation affecting the health of industrial workers.
6. To improve relationships between medicine and insurance.
7. To establish working relationships with all agencies in the state interested in industrial health.
8. To arrange for the adoption of similar activities through cooperating committees in the medical societies of the industrial counties.

To accomplish these objectives it has been recommended that the personnel of the state committees include representation from:

1. Private practice.
2. Industrial medical practice.
3. Medical representation if such exists from each of the following:
 - (a) State bureau of industrial hygiene.
 - (b) State workmen's compensation agency.
 - (c) The medical faculties in the state.
 - (d) Industrial insurance company.

A bulletin has been developed by the Council on Industrial Health to permit interchange of ideas between committees of the state societies and as a means of estimating progress.

COUNTY MEDICAL SOCIETY ORGANIZATION

The adoption of similar objectives and methods of organization by cooperating committees in county medical societies provides a sound basis for mobilizing community resources for general or special industrial health activity in accordance with local needs. Under such a plan it should be possible to establish competent sources of information about the character of local industrial operations and the important health problems of each as a first step toward early recognition and control. The resources of other community organizations interested in industrial health need investigation in order to determine how they may contribute to physical betterment of workers under enlightened medical leadership. There will be many opportunities to promote better professional training. The general public can be informed of accomplishments in industrial practice and their effect on the health of the community as a whole. An excellent means is provided whereby the interdependence of private and industrial practice is demonstrated and the activities of both augmented by consulting services in industrial hygiene developed by governmental and private agencies. Working relationships can be promptly established with the allied professional groups—industrial hygienists, safety engineers and industrial nurses.

Recent developments indicate that county society committee organization of this character can contribute materially to the provision of industrial health services for the small plant owner

and his employees interested in deriving benefit from advances in industrial medicine, surgery and hygiene but who in the past have found themselves unable to do so. Most important, it establishes a direct means of assistance to the physician who wants to know how he should conduct himself for greater and more competent participation in this field.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS. HOWARD A. CARTER, Secretary.

CONTINENTAL ULTRA SHORT WAVE UNIT MODEL SW-100, ACCEPTABLE

Distributor: Bedford Surgical Company, Inc., 1326 Fulton Street, Brooklyn.

The Continental Ultra Short Wave Unit, Model SW-100, is used for medical and surgical diathermy. Pads, cuffs, inductance coil, surgical accessories and metal electrodes are supplied as standard equipment. The shipping weight of the unit is 120 pounds.

Continental Ultra-Short Wave Unit, Model SW-100.

The firm states that the unit operates on approximately 6 meters and utilizes two tubes in a self-rectifying, push-pull, tuned plate, tuned grid oscillating circuit. The patient's circuit is inductively and capacitatively coupled to the oscillating circuit and is controlled by a split stator condenser in parallel. In tests performed by the Council the power input was found to be 750 watts and the output 280 watts; transformer temperature was 76.3 C. after the unit had been operated at full load for two hours. This temperature comes within the limits of safety prescribed by the Council.

Three radio frequency chokes incorporated in the circuit are said to reduce radio interference.

Schematic diagram of circuit.

The firm submitted data to substantiate claims for heating tissues, which were confirmed by the Council's investigation. The data are as follows:

CUFFS

Technic: Size of cuffs, 2 by 14½. Space under cuffs: Test 1, 1 inch; other tests, 1¼ inches. Space between cuffs: Test 1,

Average Temperature (F.) of Six Tests

	Cutaneous	Subcutaneous	Intramuscular	Rectal
Initial	91.96	94.68	97.88	99.6
Final	99.1	103.25	106.23	99.9

7½ inches; other tests, 7 inches. Average thigh circumference 20 inches. Average room temperature 83 F. Average room humidity 65 per cent.

The Council's clinical investigation of the unit revealed that it gave satisfactory clinical service.

The Council voted to accept the Continental Ultra Short Wave Unit, Model SW-100, for inclusion in its list of accepted devices.

GENERAL AUTOMATIC E-40 LAMP ACCEPTABLE

Manufacturer: General Automatic Corporation, Macedonia, Ohio.

The General Automatic E-40 Lamp is an infra-red generator. The source of radiation is mounted in a reflector having a polished metal reflecting surface. The reflector is 10½ inches in diameter and is placed on an adjustable stand. The maximum height of the stand is 71½ inches and the minimum collapsed height is 48 inches; the horizontal adjustment is 24 inches. Power input of the lamp is 260 watts. The weight is 24 pounds.

General Automatic E-40 Lamp.

The firm submitted data concerning the distribution of energy of the lamp compiled by a reliable investigator.

The lamp was investigated clinically by the Council and it was found to give a very intense heat at what is considered a comfortable distance with other infra-red lamps. If placed at a greater distance or angled away from the area to be treated the heat is then comfortable and pleasant. It is necessary to exercise caution when using this lamp owing to

the intense heat. It is easy to focus the heat on the patient with the adjustable arm and can be used for either side of the patient without carrying the lamp from one side to the other, as the extension is long enough for this purpose. The lamp is bottom heavy and will not tip easily.

Advertising submitted by the firm consisted of a folder which contained a description of the lamp. No therapeutic claims are made and the folder appears acceptable.

The Council voted to accept the General Automatic E-40 Lamp for inclusion on its list of accepted devices.

OTARION HEARING AID ACCEPTABLE

Manufacturer: Otation Inc., 448 North Wells Street, Chicago.

The Otation Hearing Aid was given consideration by the Council and its investigation revealed that:

The instrument consists of the following parts:

(a) Combined microphone and vacuum tube amplifier unit. Single control switch.

(b) A and B batteries enclosed in leatherette carrying case.

(c) Crystal midget receiver with molded earpiece.

The microphone and amplifier unit is in a flat molded case 3½ by 2¾ by ¾ inches, weighing 88 Gm. The control is a sliding contact on the edge of the instrument.

The A battery is a single No. 1, ES 1½ volt Burgess dry cell. The measured current drain is 41 milliamperes. The B battery is a 45 volt Burgess R 30 battery. The current drain is 0.54 milliampere. The A battery is carried in a metal sheath in the flap of the Otation.

Otation Hearing Aid.

Mechanical Features.—The instrument is simple in construction, neat and workmanlike in appearance. The tests for amplification show that while the instrument is not uniform over the whole frequency range, in view of the limitations of a miniature amplifier, it provides a fair approximation to uniformity. The tests showed that the instrument gave appreciable amplification at 8,192 cycles.

Carrying Case.—Replacement of both A and B batteries is easily effected. The overall dimensions of the battery case are 4½ by 3 by 1½ inches; total weight, 350 Gm.

Internal Noise.—The instrument is quiet for all settings of the volume control less than about three fourths full on. Above this the instrument is subject to feed back squeal unless the molded earpiece is fitted very well.

Amplification.—The following overall amplifications were shown:

	128	256	512	1,024	2,048	4,096
At normal ear threshold ¾ full on	nil	16	23	40	43	26
At normal ear threshold ¼ on....	nil	nil	20	33	30	22
At approximately 45 decibels above normal threshold, ¾ full on....	nil	12	12	25	23	21

The Council on Physical Therapy voted to accept the Otation Hearing Aid for inclusion on its list of accepted devices.

ROSE "QUARTZ-X" ULTRAVIOLET LAMP ACCEPTABLE

Manufacturer: E. J. Rose Manufacturing Company, Inc., 727-733 East Gage Avenue, Los Angeles.

The Rose "Quartz-X" Ultraviolet Lamp produces ultraviolet radiation and is in the general class of "cold" or low pressure ultraviolet generators.

A transformer, time clock, cable attachment and line cord are located in the base of the lamp. At the top of an adjustable telescoping column rising from the base is a horizontal arm which pivots about the vertical axis of the center column. It also carries a pivot to which is attached a second arm supporting the burner. A dome shaped hood made of molded plastic covers the burner terminals. The two burners supported by the aluminum reflector are parallel and consist of tubing 8 mm. in diameter. One tube is made of fused quartz and the other ultraviolet transmitting glass designated as "Corning 972 UV." (Corex).

In the center of the hood, at the back, is a three position switch lighting either the quartz, corex or both burners. The diameter of the hood is 33 cm. and the reflector is recessed 5 cm. below the rim.

Rose "Quartz-X" Ultraviolet Lamp.

The following evidence concerning the physical characteristics of the lamp was submitted by the firm:

Power consumption (on 110 volts) in watts, and the intensity of therapeutic ultraviolet radiation in microwatts per square centimeter at 24 inches were as follows:

Quartz burner	75 watts	345 microwatts
Corex burner	76 watts	156 microwatts
Both burners	94 watts	435 microwatts

During a three hour test no part of the lamp or transformer case became heated.

The spectral distribution was measured by the ultraviolet photometer and found to be:

Quartz	Corex	Both	
88.5	62	88	Between 2,000 and 2,600
10	34	10.5	Between 2,600 and 3,000
1.5	4	1.5	Between 3,000 and 3,200

in percentage of the total energy in wavelengths less than 3,200 angstroms. Physiologic tests on untanned abdominal skin gave minimum perceptible erythema in the following time:

Quartz burner	90 seconds
Corex burner	240 seconds
Both burners	75 seconds

The Council investigation confirmed these results and showed that the lamp is acceptable as a mercury glow "cold" type lamp. The spectrograms and the transmission data on the glass used in the corex tube show that the ultraviolet output is changed but little from that of the quartz tube.

On submission for the Council's consideration the lamp was named the Rose "Whole Spectrum" Ultraviolet Lamp. When advised by the Council that the name "Whole Spectrum" would not be acceptable, the firm changed the name of the unit to "Quartz-X." The Council was notified of this change by the firm April 25, 1940.

The Council voted to accept the Rose "Quartz-X" Lamp for inclusion on its list of accepted devices.

SATURDAY, SEPTEMBER 28, 1940

THE PLATFORM OF THE AMERICAN MEDICAL ASSOCIATION

The American Medical Association advocates:

1. The establishment of an agency of the federal government under which shall be coordinated and administered all medical and health functions of the federal government exclusive of those of the Army and Navy.
2. The allotment of such funds as the Congress may make available to any state in actual need, for the prevention of disease, the promotion of health and the care of the sick on proof of such need.
3. The principle that the care of the public health and the provision of medical service to the sick is primarily a local responsibility.
4. The development of a mechanism for meeting the needs of expansion of preventive medical services with local determination of needs and local control of administration.
5. The extension of medical care for the indigent and the medically indigent with local determination of needs and local control of administration.
6. In the extension of medical services to all the people, the utmost utilization of qualified medical and hospital facilities already established.
7. The continued development of the private practice of medicine, subject to such changes as may be necessary to maintain the quality of medical services and to increase their availability.
8. Expansion of public health and medical services consistent with the American system of democracy.

THE COORDINATING COMMITTEE FOR MEDICAL PREPAREDNESS

An executive order was issued on September 19 setting up, with the approval of the President, under the Council of National Defense, a subordinate body to the council to be known as the Medical and Health Committee. The chairman of this organization is Dr. Irvin Abell, who is also chairman of the American Medical Association's Committee on Medical Preparedness. The order defining the establishment of the committee and its duties follows:

Pursuant to the authority vested in it by section 2 of the act of Aug. 29, 1916 (39 Stat. 649), the Council of National Defense, with the approval of the President, hereby establishes as a subordinate body to the council a committee to be known as the Health and Medical Committee. The committee shall consist of the following members: Dr. Irvin Abell, who shall be chairman, the Surgeon General of the Army, the Surgeon General of the Navy, the Surgeon General of the Public Health Service, and the chairman of the Division of Medical

Sciences of the National Research Council. Vacancies occurring in the membership of the committee shall be filled by appointment by the council with the approval of the President. The members of the committee and of such subcommittees as may be formed by the committee shall serve as such without compensation but shall be entitled to actual and necessary transportation, subsistence and other expenses incidental to the performance of their duties.

It will be the responsibility of the committee to advise the Council of National Defense regarding the health and medical aspect of national defense and to coordinate health and medical activities affecting national defense. In carrying out its functions the committee may (a) utilize, to the extent that such facilities are available for such purpose, the laboratories, equipment and services of the Medical Departments of the Army and Navy, of the Public Health Service and of other government institutions and (b) within the limits of the appropriations allocated to it, to contract with and transfer funds to such institutions and to enter into contracts and agreements with individuals or educational or scientific institutions for studies, experimental investigations and reports.

The committee shall promulgate rules and regulations for the conduct of its work, which rules and regulations shall be subject to the approval of the council and the President.

This executive order brings to a favorable conclusion a cause for which officials of the Association, representing the Board of Trustees and the House of Delegates, have labored persistently since the annual session in June. The work of the American Medical Association in the development of personnel for the military services, for industrial medicine and for maintaining the health of the people can be carried forward with far greater efficiency through the establishment of some relationship directly with the government. The work of the National Research Council in the investigation of procedures to be carried out for military purposes, in the development of information to be circulated to the medical profession and in the standardization of military medical procedures will also be greatly facilitated by this coordinating committee.

No doubt announcements will issue in the near future from the coordinating committee indicating the nature of its activities and the cooperation that will be required from the medical profession. Under the leadership and with the membership of the committee that has been established, the medical profession may give to this committee its complete confidence and an assurance of full cooperation.

MEDICAL CARE AND REFUGEE CHILDREN

Already many children of British scholars have come to this country and are under the care of American teachers in institutions of higher education who have volunteered their assistance. In some instances physicians have wished to participate in this charitable activity, and a few have written to THE JOURNAL requesting information as to how they may secure the children of British physicians. For the present, all such activities are being conducted by the United States Committee for the Care of European Children, Inc., 215 Fourth Avenue, New York City. This agency will give any physician who is especially interested, and who will write to it, specific information.

A physician in an Ohio community was called to attend a small child who had been brought to this country from England for placement in an American home to escape the dangers of war. This physician found that the child was suffering from badly diseased tonsils and adenoids. He recommended an operation but was advised that the surgical procedures contemplated could not be undertaken lawfully until consent was obtained from the child's parents in England. As more and more European children are placed in American homes the problem that confronted this physician will necessarily constantly recur. Any unnecessary delay in providing medical care for the children would be most unfortunate. The United States Committee for the Care of European Children, in which now centers the responsibility of securing American homes for the young refugees, has given this matter of authorization of medical care considerable thought. The committee realizes the importance of the matter and is working on a plan to effect a definite solution to the problem. Pending the completion of this plan, however, the committee thus expresses the view that there need not now be any such delay as was suggested to the Ohio physician:

Pending a more permanent arrangement, the United States Committee and any foster parents, however, are not left completely remediless. We feel that there is a degree of factual background which would enable a foster parent, on the basis of general American law, to consider himself as acting in loco parentis. Among such factors are that the English parents of their own volition sent their child to an American home and assumed all the risks inherent therein, that the American foster parents have taken the child into their home, have supported it, have cared for it, and generally have exercised custodial powers over it. Certainly, it would seem such foster parents could exercise their rights over the child as against any other individuals, with the exception of the child's actual parents. Bearing such factors in mind it would appear likely that American courts would hold that the American foster parent, having assumed all these rights, duties and obligations, would likewise have the power to consent to any necessary medical or surgical treatment of the child.

We feel that there are also two further mitigating circumstances. In the first place it is highly unlikely that the question would ever be raised except by the English parents themselves and it is extremely doubtful, in view of all the circumstances, that they would complain. In the second place, we feel that an American court would be reluctant to hold the United States committee or the foster parents liable for such a given consent when the whole picture of this emergency child care movement was adequately and forcefully presented. If, on the other hand, the foster parents were negligent in handling the matter they should be held liable.

If an American family which receives a European child into its home agrees in so doing to furnish the child with the necessities of life, as probably is the case, there may arise a question of legal responsibility if a delay in furnishing medical care, certainly one of the necessities of life, results in injury to the child even though that delay may be occasioned by uncertainty as to the right on the part of the foster parents to authorize the needed medical or surgical attention. This whole matter, while only one of the many problems incident to the evacuation of European children to this country, is of sufficient importance to justify the hope

that whatever doubts may now exist as to the right to give a valid authorization for the rendering of necessary medical care to the children may be removed without delay.

BODY BUILD AND HYPERTENSION

While the prevailing opinion assumes a constitutional factor in hypertensive diseases, there is no unanimity of opinion on the relation between gross body structure and blood pressure. Robinson and Brucer¹ based their study of this question on a statistical analysis of the periodic health examination records of 3,658 unselected men and women (age concentration of the 1,861 males between 31 and 55 years, that of 1,797 females between 27 and 50 years) who were classified into linear, or narrow chested, and lateral, or broad chested, groups by means of a simple anthropometric index found by dividing chest circumference by standing height and ignoring body weight. Persons of linear build were defined as having a chest/height ratio of less than 0.50, their chest measurement being less than half their height; those of lateral build showed on the average an index of 0.59 or over. A gradual increase in chest circumference was noted for both men and women before the age of 50, with a decrease thereafter. Extremely large chests were not observed in the old age groups. This suggests a high death rate in men with large chests during the previous decades. Men of linear build with chest/height ratios of 0.47 and under showed an average systolic pressure of 114 mm. and an average diastolic pressure of 70 mm. In the average lateral type man the systolic pressure was as high as 130 mm., the diastolic 79 mm. The median and modal systolic pressures rose from 110 mm. in men of linear build to more than 118 mm. in those of lateral constitution; median and modal diastolic pressures rose from 70 mm. in the linear body type to over 77 mm. in the lateral. The tendency in women was similar.

The difference in susceptibility to hypertension in persons of contrasting body build extremes was unusual. Only 4 per cent of the men of linear body structure had systolic pressures over 140 mm., whereas 22 per cent of the laterally built men were definitely hypertensive. Only 2 per cent of the women of the linear type as compared with 27 per cent of those of the lateral type had systolic pressures over 140 mm. Forty-three per cent of the men of linear build but only 17 per cent of those of lateral build had low diastolic pressures under 70 mm., while 60 per cent of the women of the linear constitution but only 34 per cent of those of lateral build showed a similar diastolic trend. Low blood pressures of either kind were accordingly found predominantly in persons of linear body structure and high pressures in the opposite type. Men of the lateral, or broad chested, type had more than four times the expectancy of systolic hypertension and

1. Robinson, S. C., and Brucer, Marshall: Body Build and Hypertension, *Arch. Int. Med.* 66: 393 (Aug.) 1940.

seven times that of diastolic hypertension than men of linear, or narrow chested, gage.

In women the ratio was even more striking, an eleven times greater systolic hypertension expectancy and an eight times greater diastolic hypertension expectancy in those of the lateral type. Moreover, persons of broad build showed higher pressures than persons of narrow build at all age levels. Men of linear build did not show an increased systolic pressure until late in life, women not until after the age of 50. Men of linear type maintained about the same diastolic pressure throughout life. Women of the linear type showed an increase in mean diastolic pressure but not to so great an extent or at such a high level as women of the lateral type. Accordingly the incidence of low systolic pressure was high among persons of the linear build at every age as compared with that of persons of the opposite body build. Diastolic pressures showed much the same tendency. Since the authors believe in a correlation of hypertension with the lateral, or broad, build and of low pressure with the linear, or thin, build they regard the hereditary predisposition to normal pressure and hypertension as an established fact.

Current Comment

PLAGUE IN THE UNITED STATES

The first recorded appearance of plague in the United States occurred in San Francisco on March 6, 1900. In reviewing developments in this country since that time, Hampton¹ points out that human cases of the disease have been reported in eight states in the following chronologic order: California 1900, Washington 1907, Louisiana 1914, Florida 1920, Texas 1920, Oregon 1934, Utah 1936 and Nevada 1937 (the last human case was reported from Millard County, Utah, on Dec. 4, 1939). In all, 499 human cases with 314 deaths were recorded between 1900 and Jan. 1, 1940. Between 1934 and 1939, however, only fifteen cases of plague with six deaths have been reported in the United States, and all of these but four cases and one death occurred in California. This record exists in spite of the fact that plague infection has been demonstrated in fourteen species of ground squirrels and in red squirrels, tree squirrels, flying squirrels, wood rats, kangaroo rats, field mice, prairie dogs, chipmunks, marmots and one cotton tail rabbit, in addition to the more common infection in rats. The reason this widespread sylvatic distribution has not resulted in more human cases may be in part explained by the sparse human settlements in those regions of extensive wild life infection. However, as records already available show, wild rodent plagues may spread unnoticed over wide areas unless intensive measures are taken to detect their presence. Further spread of the infection eastward through a rodent and human population of insufficient density to give rise to explosive epidemics may, however, eventually bring the disease within striking distance

of the rat and human populations of large cities. Here the disease may become epidemic in the presence of a sufficiently high population of rats and a sufficiently high flea index to provide favorable conditions for human infection. Furthermore, as rightly emphasized, the relatively small number of cases of plague during the past forty years does not indicate that too much prominence has been accorded that disease, since its ability to surmount the barrier of quarantine, its persistence and gradual biologic and geographic spread and the difficulty of eradicating it must continue to place it high in the rank of public health problems. The extensive available knowledge of plague prevention and control and the exercise of constant vigilance should guarantee, however, that it need not be permitted to occur in epidemic form in any locality in the United States.

INFANTILE BERIBERI IN HONG KONG

According to a report by Fehily,¹ an investigation at the Infant Welfare Center in Hong Kong revealed that 18 per cent of the infants on first admission showed clinical signs of beriberi, placing this disease immediately after respiratory and cutaneous disorders in order of frequency. It was further found on examination that 81 per cent of those breast fed by mothers whose milk was peroxidase negative (a specific test for vitamin B₁ avitaminosis) were found to show signs of infantile beriberi of varying severity. Previous experiments, Fehily points out, have shown that the milk of women with a B₁ avitaminosis is not only deficient in this vitamin but also actively toxic. Others have succeeded in isolating methylglyoxal from the milk and urine of B₁ avitaminotic women, which may, it is suggested, represent the toxic factor. Although presumably vitamin B₁ deficiency is more common in Hong Kong than in most sections of this country, the observations made there may prove of great value everywhere.

PHYSIOLOGY OF INTERCOSTAL NERVE

The physiologic explanation for the appearance of abdominal symptoms in the presence of thoracic disease, the most notable of which is the referred pain over the appendix sometimes actually resulting in unnecessary surgery, has not been entirely clear. Kahn,¹ in a recent report based on investigations of the intercostal nerves of dogs, found that stimulation of the central end of any intercostal nerve causes a reflex inhibition of respiration and effects a concomitant drop in blood pressure. The lower intercostal nerves (seventh to twelfth) elicit a greater response than do the upper ones. Likewise it was shown that stimulation of sensory or intercostal fibers in the diaphragm causes reflex contraction of the abdominal musculature through a reflex connection with other lower intercostal nerves. These observations contribute to the understanding of the physiologic mechanisms involved in referred pain and the muscular rigidity in the lower abdominal quadrant resulting from involvement of the base of the lung by various pathologic processes.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

MEDICAL PARTICIPATION IN SELECTIVE SERVICE

CHARLES B. SPRUIT

Lieutenant Colonel (M. C.), General Staff Corps, United States Army; Medical Adviser to the Joint Army and Navy Selective Service Committee

Washington, D. C.

The nation through its representatives in Congress has again decided to increase the armed forces of the United States in accordance with a fair and just system of compulsory selection in order that the obligations and privileges of military training and service may be shared generally. The whole purpose of Selective Service is to procure men for our land and naval forces with a maximum of efficiency, economy and equity, and with a minimum of disturbance to the social, economic, industrial and agricultural life of the nation.

THE CHARACTER OF THE SELECTIVE PROCESS

The salient characteristic of selective service will be that of democracy in action. Men will be registered, classified and selected by boards composed of their neighbors who are empowered to determine for each registrant his liability for military service with fairness to him, the community and the nation. The state and national Selective Service headquarters will be directing and coordinating agencies.

THE OPERATION OF SELECTIVE SERVICE

In general terms, the operation of the Selective Service is as follows: On registration day all men between certain ages will register at their polling places. The registration cards will be numbered serially by local boards. A national lottery will be held in Washington to determine the order in which men in each local board area are liable for selection for military service. The board then sends questionnaires to the registrants. On a basis of his completed questionnaire, the board tentatively decides whether the registrant should be classified as available for military service or should be put in a deferred classification. If the board classifies him as available, it causes him to be examined by its examining physician; if found physically fit, he is definitely classified as available. The registrant may appeal his classification and have his appeal decided by a board of citizens of his state. National headquarters on advice from the armed services will issue a general call on each state to fill its quota. Each state headquarters will issue a similar call to each local board. The local board then selects the required number of available registrants in the order determined by the lottery and orders them to report at a fixed time to a military induction station. Each registrant who is physically and morally acceptable to the military is thereafter inducted into the military service.

EXEMPTIONS

The law provides in general that personnel of the armed services and alien diplomatic officials, consuls and consular agents shall not be required to register.

Exemption from registration obviously precludes selection and induction.

It also provides for certain exemptions from service for ministers of religion and theological students in particular, and for persons who have completed or who are in process of completing certain years of service in the Regular Army or active National Guard. Persons in this category, however, must register.

DEFERMENTS

Provision has been made for the deferment, but not the exemption from service, of additional categories of persons generally stated as follows: (a) the Vice President, governors, legislators and judges of national and state governments; (b) any person holding an office whose continuance therein is found to be necessary in the maintenance of the public health, safety or interest; (c) those whose employment in industry, agriculture or other such occupation is found to be necessary to maintain national health, safety or interest; (d) those with dependents, and finally (e) those men found physically, mentally or morally deficient or defective.

DEFERMENTS FOR STUDENTS

A general deferment from induction for service and training has been provided during the school year 1940-1941 for any person who has entered on attendance in a course leading to a degree at a college or university which grants a degree in arts or science.

NO GROUP DEFERMENTS

The law specifically provides that no deferments will be made in the case of any individual except on the basis of the status of that individual, and further that no deferment shall be made of individuals by occupational groups or of groups of individuals in any plant or institution. It will thus be seen that the deferment of any individual whose exemption or deferment is not specifically provided by law will be decided by local boards on the merits of the case and the demonstration of the necessity for deferment. It is believed that such necessity can be demonstrated for residents and interns in hospitals, for key technical personnel in hospitals and laboratories and for officials in state, county and local health departments, and similar participants in matters of the public health.

CLASSIFICATION

Every registrant will be classified by local boards after due process into one of four general classes:

- Class 1. Those available for service.
- Class 2. Those deferred because necessary in a civil occupation.
- Class 3. Those deferred because of dependent relatives.
- Class 4. Those deferred by law or because obviously unfit for service.

THE ROLE OF THE PHYSICIAN

Inauguration of selective service brings a new responsibility to the medical profession and another opportunity of service to the nation. The role of the physician in the Selective Service mechanism will be

to examine, to find, to evaluate and to recommend. The local board and the appeal board will determine the final classification of all registrants. It is believed that the participation of the physician of the community in determining the physical qualifications of registrants will promote confidence in the fairness of the system and permit of a more accurate determination of the ability of a man to perform military service. The intimate knowledge that the local physician has of the members of his community should be of marked assistance not only in the determination of physical fitness but also in the detection of malingering on the part of men seeking to evade service.

There is a strong feeling in Congress and throughout the nation that, since men are being called to military service at great personal sacrifice, Selective Service officials should be men who are willing to make an important sacrifice by contributing voluntary service, and that a process based on devotion to the national interest should not deteriorate into a job holding organization. It appears very probable, therefore, that no compensation will be provided for members of local boards, boards of appeal, medical advisory boards, examining physicians or similar officials. Clerical employees will unquestionably be paid and will be thoroughly competent in order to free officials of petty clerical routine and leave them free to devote their time to their important responsibilities. Provision, however, has been made to furnish the supplies required in physical examination and to pay for those procedures necessary for the determination of a man's physical fitness, such as laboratory or x-ray examination.

PHYSICAL STANDARDS

It is the present intention of the armed services to accept for induction only those men who are fit for full duty. The physical standards of Selective Service, therefore, will be those of the using services, which in the case of the Army are substantially those now governing enlistments.

It is probable that all men inducted during the coming months will be sent to the Army for training and service. Army standards will accordingly be used. When men are required by the Navy and Marine Corps, the physical standards of those services will be issued and used. It is the general policy that men accepted by the Army for induction shall be immediately available for full training and service and be free from acute communicable disease.

Many physicians in the Selective Service process will be confronted with a new criterion of judgment. The doctor in civil life is concerned in treating his patients so that they may continue their present modes of living and physical endeavor. The criterion of judgment of Selective Service is that the man shall be capable of performing full military service in any type of organization. This criterion may be epitomized by stating that the man, after proper hardening, must be able to walk 15 or 20 miles, carrying 50 pounds on his back, without taking harm to himself in the process.

Since the decision as to the ability of any given registrant to perform such duty depends on the professional judgment of each physician who examines the man, it must be anticipated that there will be honest differences of professional opinion between the examining physicians of the local board and the examining physicians of the medical advisory boards; also between the examining physicians of Selective Service and the examining physicians on the military examining boards. These

will be honest differences of opinion and must be expected and accepted. It is believed that they will be fewer than occurred in the World War, since the same standards of physical examination will be used by Selective Service and by the military examining boards.

LOCAL BOARDS

The basic responsibility of administration and determination will rest on the local boards, whose members will be selected from each of some 6,500 communities. These local boards will determine all deferments and exemptions and make the final and crucial classification, after local physical examination, which makes the registrant available for induction.

THE LOCAL EXAMINING PHYSICIAN

The physical examinations of Selective Service will be made by local examining physicians, who act as agents of the local boards for this purpose. When necessary, additional examining physicians may be appointed by the local board. The local examining physician will examine all registrants sent to him by the local board according to the standards of physical examination which will be furnished him. He will note all deviations from the normal on physical examination forms and then interpret them in the light of the physical standards and in terms of the ability of the registrant to perform full military service. Thereafter he will record his recommendations to the local board as to the physical qualifications of the man to do full or limited military service. If the registrant possesses defects that disqualify him for any military service, that fact likewise will be entered. In those cases in which the local board has appointed additional examining physicians, it may be feasible in certain communities to form an examining group to facilitate and expedite the examinations.

MEDICAL ADVISORY BOARDS

Medical advisory boards will be appointed by the President, on the recommendation of the state, to provide an agency of advice and assistance to examining physicians and to assist appeal boards in determining matters of physical fitness which have been appealed from the decision of the local board by the registrant or by the government agent. The medical advisory boards will as far as practicable comprise internists, ophthalmologists, otolaryngologists, orthopedists, surgeons, psychiatrists, clinical pathologists, radiographers and dentists.

MALINGERING

The experience of Selective Service during the last war showed the necessity of constant vigilance to detect malingering. Many men descended to self mutilation and numerous other more ingenious but less harmful subterfuges to escape military service. Malingerers will doubtless be encountered in the coming operation of Selective Service. Regulations on physical standards mention many of the more common practices used by malingerers to feign disability and describe methods by which these may be detected.

THE MEDICAL TASK

The fall increment of some 400,000 men will be distributed according to quotas to the several states and by each state headquarters to the local boards in that state. On the assumption that these 400,000 men will be equally divided among the 6,500 odd local examining boards, and utilizing the World War percentage of rejections by examining physicians of Selective Service

and of the Army, there will be about ninety men per local board for physical examination. As these men will not all be inducted immediately but will be called up during the following three or four months, the average examination load on each board will probably be between twenty and thirty men per month. These calculations are not applicable to each local board because the quota assigned to a local board takes into consideration certain credits to that community accruing from men presently in the regular services or active National Guard. The total appeals on physical grounds during the World War indicate a lesser load on medical advisory boards. The additional number of cases sent up for advice by local examining physicians is not known.

STATE HEADQUARTERS

The state headquarters operating under the governors of the several states are charged with the organization and operation of the Selective Service system within the respective states under the policies and procedures authorized by the President. For each state the President will designate one or more officers of the Medical Reserve Corps of the Army and Navy as medical assistants on the staffs of the several governors. They will assist the state authorities in the supervision and coordination of medical examinations throughout the state. They will establish and maintain liaison with all examining physicians and members of medical advisory boards, hold regional meetings for them to promote critical discussion and analysis of the medical problems of selective service, and visit medical advisory boards, local boards and examining physicians to advise and assist all concerned with physical examinations. They will keep the necessary records and statistical analyses of the operation of the medical function of Selective Service within the state.

NATIONAL HEADQUARTERS

The National Selective Service Headquarters in Washington will contain a compact medical division, which will assist the director of Selective Service in the determination of policy on medical matters and have general direction and coordination of the medical functions through the state headquarters and the medical assistants in each state.

INTANGIBLE BENEFITS OF SELECTIVE SERVICE

The training and service of hundreds of thousands of young men of the nation during the coming years, the improvement in their physical condition resulting from good food, regular hours, supervised physical endeavor and healthful environment, as well as a revival of that feeling of national unity which seems ever to be a part of a great national effort, will not be the only benefits which the nation will derive from Selective Service. There are certain other dividends which will be worth while. It is expected that the analyses of the reports of physical examinations and other records of Selective Service will make available many new data of sociological and medical importance. The occurrence of disease and disability as to character, locality, age group, color and nativity will give us a new measuring stick by which to judge the efficacy of the many and varied health programs that we have carried on in the last twenty years and will assist in the preparation of new plans for the future. These analyses will further disclose the physical fitness of the new generation and provide us with a current and more accurate measure of the available manpower of the country against "The Day" we pray may never come.

NEW NAVAL MEDICAL OFFICERS

The following candidates have been appointed assistant surgeons of the U. S. Navy with the rank of lieutenant (junior grade) to rank from July 15:

John W. Thomas, Phoenix, Ariz.
Charles J. Allen, Milwaukee.

Jesse H. Sutor, Memphis, Tenn.
Leonard A. Becker, Chicago.

OHIO COMMITTEE MEETS

The committee on medical preparedness of the Ohio State Medical Association held a meeting at the association headquarters in Columbus, August 18, with seven of twelve members present in addition to the chairman, Dr. H. V. Paryzek, Cleveland. Dr. Fred W. Rankin, Lexington, Ky., member of the national committee for the Fifth Corps Area, attended the meeting. Plans were made to urge all physicians to complete and return the questionnaire of the American Medical Association and to request county societies to appoint preparedness committees. At the request of Governor Bricker, the committee discussed medical factors which would be involved in the selection of draft boards and submitted recommendations for his consideration.

ORGANIZATION SECTION

WOMAN'S AUXILIARY

Georgia

The executive board of the woman's auxiliary to the Medical Association of Georgia met in Atlanta with the advisory committee from the association, the latter group approving the year's projected work for the auxiliary at this time. Dr. James N. Brawner, of Atlanta, chairman of the advisory committee, presided over the meeting. Mrs. H. G. Banister, of Ila, recently installed president of the auxiliary, presented an outline of the work to be undertaken during the year. It was decided to sponsor the writing of health plays, and Dr. Brawner offered a prize of \$10 for the best play submitted.

Utah

Mrs. E. L. Van Aelstyn discussed "What the Law Expects of the Physician" and presented the plan of the Utah Medical and Hospital Benefit Association at the March meeting of the auxiliary to the Carbon County Medical Society in Price.

The auxiliary to the Salt Lake County Medical Society has placed *Hygeia* in all the hospitals in Salt Lake City. Mrs. John Z. Brown, president of the auxiliary, presided at the recent meeting when the statue of "Hygeia," which was won as a prize by the auxiliary in the recent Hygeia Contest, was unveiled.

Dr. George Fister and Mr. W. M. Tibballs discussed the plan of the Utah Medical and Hospital Insurance before public meetings under the auspices of the auxiliary to the Utah County Medical Society in Provo recently.

At the February meeting of the auxiliary to the Weber County Medical Society in Ogden, Mrs. Claude L. Shields spoke on "Budgeting Your Time."

Virginia and West Virginia

The woman's auxiliaries to the West Virginia and Virginia medical associations held a joint annual meeting in White Sulphur Springs, W. Va., July 29-31. Mrs. V. E. Holcombe, president of West Virginia auxiliary, also national president, and Mrs. H. A. Latane, president of the Virginia auxiliary, presided over the business meetings of their respective auxiliaries. There were 114 registered from West Virginia and 119 from Virginia.

On West Virginia Day a luncheon was given for both auxiliaries, with Mrs. Holcombe acting as hostess to about thirty distinguished guests at the speakers' table and 200 auxiliary members. Dr. Hugh Trout, president of the Medical Society of Virginia, and Dr. Frank Longfitt, president of the West Virginia State Medical Association, were among the honored guests. The principal address was given by Mrs. Charles P. Corn, president of the Southern medical auxiliary.

At the annual election of officers for the two states, Mrs. H. V. Thomas took office as president of the West Virginia auxiliary and Mrs. Griffin W. Holland as president of the Virginia auxiliary.

At the annual dinner Governor and Mrs. James Price of Virginia and Governor and Mrs. Frank Holt of West Virginia were present. Both governors gave short addresses.

MEDICAL ECONOMIC ABSTRACTS

MEDICAL CARE IN GEORGIA

After making a thorough study of medical facilities and needs throughout the state, the Medical Association of Georgia conducted a symposium on the Problems of Medical Care in Georgia in Savannah, April 24.¹ The statistical study which laid the factual basis of the symposium included a complete survey of the state to determine "the total population per county serviced by one physician, the number of whites per county serviced by one physician, and the square miles covered by one physician per county. These statistics were correlated with the net taxable values per county." This study was conducted by Dr. Alfred A. Weinstein and Dr. C. W. Roberts from the Emory University School of Medicine.

It was found that there was a fairly close correlation between the county taxable values and the number of physicians in the county. "The two extremes were as follows: Chattahoochee County with net taxable values of \$250,630 had no physicians; Fulton County with net taxable values of \$229,775,695 had 653 physicians." When this correlation was graphed it became evident that the "number of physicians in a county begins to rise sharply only after the net taxable values in the county increase over \$2,000,000."

There has been a positive decrease of 144 in the number of physicians in Georgia in the years from 1931 to 1936. This decrease has been largely in the low income rural areas where there were already the fewest physicians. "There were 2,285 physicians engaged in general practice in Georgia in 1938. In the rural areas there is one physician per 1,800 population, in the urban areas 1:1,000, and for the state as a whole 1:1,560. In the United States the ratio was 1:785." It is suggested "that certain counties may see fit to partially subsidize a prac-

itioner to care for the medically indigent, and simultaneously permit him to carry on private practice among those who can afford to pay."

A study of the distribution of hospitals showed that Georgia has a lower ratio of hospital beds per population than most of the states. This is largely due to the low incomes which prevail. Some estimates have fixed the per capita income in Georgia as low as \$146 annually. Dr. T. F. Abercrombie, director of the Georgia Department of Public Health, recognizes that any widespread distribution of hospitals is liable to overlook maintenance costs and expect to obtain these from pay patients. Group hospitalization, while it has proved helpful, does not meet all emergencies. "During an influenza epidemic" in Atlanta "when hospitals were overflowing because people who had paid their hospitalization fee demanded benefits whether hospital care was necessary or not it was almost impossible to get emergency cases admitted." He also finds that malnutrition is an extremely serious problem and that "If the whole population were adequately nourished our public health and medical care programs would be simplified immensely."

There was considerable discussion of hospital programs and plans for the care of the indigent. The discussion of hospital planning was based on illustrations from several counties that had recently constructed hospitals largely under the direction of the county medical society. The problem of adequately staffing these is still an important one. Prepayment plans under the direction of organized medicine were suggested in accordance with the resolutions adopted by the House of Delegates of the American Medical Association.

It was pointed out that education of individuals on the necessity of seeking good medical care and avoiding self diagnosis and self treatment through "patent medicines" and patronage of quacks is of paramount importance.

1. Symposium on the Problems of Medical Care in Georgia, J. M. A. Georgia 29: 341 (July) 1940.

THE GENERAL PRACTITIONER AND HIS HANDBAG

(From the *North Carolina Medical Journal*, June 1940)

In his recent book *The Patient's Dilemma*, Dr. Hugh Cabot quotes the following statement from Dr. Morris Fishbein: "Obviously, 85 per cent of the diseases for which patients consult doctors are of the type which the general practitioner can handle with the amount of equipment that he can carry in a handbag." Dr. Cabot's comment is "We shall, I think, be on sound ground in asserting that this statement never was true and that it is even less true today. . . : I am unaware of any evidence . . . acceptable to any scientific body which would support Dr. Fishbein's allegation."

In an effort to find out which of these views was correct, five Winston-Salem medical men tabulated an average of 200 consecutive cases each. Of the 1,000 patients thus reviewed 848, or 84.8 per cent, had been cared for without any other equipment than the contents of a handbag. A modern doctor's handbag, be it remembered, contains at least a blood pressure apparatus, a stethoscope, a hypodermic syringe, an otoscope, an ophthalmoscope, a transillumination light, a blood counting apparatus, glass slides, a hemoglobin scale, a pleximeter, tongue depressors, Wassermann tubes, culture tubes, and a few other odds and ends.

In tabulating these cases, every patient who had to have a basal metabolism reading, an x-ray examination, an electrocardiogram, an operation or a surgical consultation or who was referred to a clinic for a diagnostic survey was included in the referred group even if the doctor had his own basal metabolism apparatus or electrocardiograph. A considerable number of these referred patients, it should be noted, were beyond real help from any medical source: for example, some with arthritis, some with incurable mental disease, and a few who literally enjoyed poor health too much to exchange it for an active existence.

The lowest proportion of patients cared for unaided by an individual doctor was 82 per cent, the highest 89 per cent. The average of 84.8 per cent is certainly close enough to 85 to be acceptable to most scientific bodies as supporting Dr. Fishbein's statement.

MEDICAL SERVICE ASSOCIATION ORGANIZES

At a meeting of the members of the Medical Service Association of Pennsylvania, held on April 3, 1940, in Harrisburg, the amendments to the by-laws of the association suggested by action of the house of delegates at its special meeting held Feb. 28, 1940, were adopted. The following members were in attendance: Louis H. Clerf, Walter F. Donaldson, Chauncey L. Palmer, Lester H. Perry, David W. Thomas, A. Alfred Wasserman and G. Harlan Wells. Robert L. Anderson and Robert V. White were absent on account of illness.

Immediately following the membership meeting a meeting of the board of directors was held at which the following officers were elected: president, Chauncey L. Palmer, Pittsburgh; first vice president, Louis H. Clerf, Philadelphia; secretary, Lester H. Perry, Harrisburg; treasurer, Robert L. Anderson, Pittsburgh; members of executive committee, Walter F. Donaldson, Pittsburgh, David W. Thomas, Lock Haven, Dr. Palmer, and Mr. Perry.

Three problems were referred to the Executive Committee: (1) The problem of alternative plans on the deductible or limited service principle; (2) the problem of the maximum benefits allowed in any one year, and (3) the wording of the section in the Participating Physician's Agreement to cover the S3 assessment.

At the present time the executive committee is working on these three problems with the objective that within the very near future the entire plan in its revised form will be presented to the state insurance commissioner for his approval.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Personal.—Dr. John B. Plum, Nashville, Tenn., has been appointed to the staff of the state department of health, succeeding Dr. Charles J. Westover, Anniston, as tuberculosis clinician. The latter has resigned to enter private practice in Michigan, newspapers reported.

Society News.—Drs. James A. Becton, Birmingham, and Merle E. Smith, Parrish, addressed the Walker County Medical Society, Jasper, August 9, on "Shock in the Treatment of Certain Mental Diseases" and "The Sulfonamides in Therapy" respectively. Dr. James R. Garber, Birmingham, discussed problems in obstetrics before the society recently.

Medical Seminar.—The Jefferson County Medical Society sponsored a seminar in Birmingham, September 16-17. Among the speakers were Drs. Marion Arthur Blankenhorn, Cincinnati; Francis Bayard Carter, Durham, N. C.; George Argale Harrop, Princeton, N. J.; Willis D. Gatch, Indianapolis; William Wirt Waddell Jr., Charlottesville, Va., and John Albert Key, St. Louis.

ARKANSAS

Personal.—Dr. Louis K. Hundley, Warren, formerly health director of Bradley County, has been assigned to the trachoma control service of the state board of health.

Changes in Health Officers.—Dr. Albert W. Thompson, Bentonville, has been appointed medical director of the Benton County health unit, succeeding Dr. James B. Tucker, resigned. —Dr. Neil E. Compton, Warren, has been appointed director of the Bradley County health unit. —Dr. Raymond E. Smallwood, Little Rock, has been named in charge of the Garland County health unit.

CALIFORNIA

Long Incubation Period in Rabies.—An incubation period of 113 days for rabies was recently reported for a dog in San Francisco, the longest incubation period recorded in the city's history of the disease. According to the health department, this is important in view of the fact that the ordinary quarantine period in California for any dog bitten by a rabid dog is three months. On April 16 a pet dog was bitten by a stray dog. The latter died a few days later of rabies confirmed on microscopic examination of the brain. The pet dog showed a slight wound on the left hind leg and was taken to the public pound, April 19, where it remained in solitary confinement until July 19. Physical examination of this animal on release gave negative results. It is positively stated that it had not come in contact with other dogs. Later in July the animal was returned twice to the pound for clipping and bathing. On August 3 the dog was admitted to a private veterinary hospital because of illness which became gradually worse, and it died August 6 of rabies confirmed by microscopic examination of the brain. In the interval from July 19, when it was released from the pound, to August 3, when the animal became ill, the dog did not come in contact with other animals, having been confined on its owner's premises with the exception of the two return visits to the pound, it was stated. Up to May 15, 1939, when a positive examination for animal rabies was reported, San Francisco had been free from this disease for many years. Since that time there have been sixty-six cases.

DISTRICT OF COLUMBIA

Emergency Facilities.—A booklet has been compiled by the Health Security Administration, Washington, entitled "Emergency Facilities." It is a directory of information on hospitals and ambulances, with particular reference to their locations and methods of immediate contact, and covers the emergency facilities in Washington, nearby Maryland and Virginia. Telephone numbers are listed and various services are classified, making the general information available to the public at large and acting as a time-saver to telephone operators, personnel of police departments, fire departments, hospitals, private physicians and nurses, ambulance attendants and others. The booklet is available on request to the Health Security Administration, Health Security Center, 1823 L Street, N.W., Washington.

FLORIDA

Personal.—Dr. Lamar L. Lancaster, Lake Wales, has been appointed superintendent of the Polk County Hospital, Bartow, succeeding Dr. William L. Hargrove. The latter resigned after fifteen years' service to take over the city hospital on a dollar a year lease basis, newspapers reported.

Annual Regional Meetings.—The fourth annual meeting of the Northeast Medical District of the Florida Medical Association will be held at the Ocean Dunes Club, Daytona Beach, October 3, with the following speakers, among others:

Dr. George M. Green, Daytona Beach, Amnesia and Short Labor.
Dr. Theodore F. Hahn, DeLand, Staphylococcus Toxoid.
Dr. John W. Snyder, Miami, The Splenomegalias with Surgical Indications.

At the fourth annual meeting of the North Central Medical District in the Blanche Hotel, October 4, Lake City, the speakers will include:

Dr. Thomas H. Wallis, Ocala, Use of Endocrines in Treatment of Functional Menstrual Disorders.
Dr. William C. Thomas, Gainesville, A Review of 550 Consecutive Cases of Pregnancy with Hospital Delivery.
Dr. Council C. Rudolph, St. Petersburg, Roseola Infantum.

The fourth annual meeting of the Northwest Medical District at the San Carlos Hotel, Pensacola, October 5, will be addressed by the following, among others:

Dr. James H. Pound, Tallahassee, Case Report of Staphylococcus Septicemia Treated with Sulfathiazole.
Dr. Rayburn N. Joyner, Marianna, Pectin in the Treatment of Chronic Ulcers.
Dr. William H. McCullagh, Jacksonville, Treatment of Some of the Common Neuropsychiatric Disorders.

ILLINOIS

Society News.—Eldridge T. McSwain, Ed.D., associate professor of education, Northwestern University, Evanston, addressed the Peoria City Medical Society in Peoria, September 10, on "Education's Contribution to Adolescence in a Democracy."—The Sangamon County Medical Society was addressed in Springfield, September 5, by Dr. Carl-Gustaf D. Tillman, Topeka, Kan., on "Medical Aspects of Chronic Alcohol Addiction."

Free Laboratory Diagnostic Service.—A limited laboratory service in the diagnosis of cancer is now available from the state department of public health to the physicians of Illinois. Biopsy specimens taken from poor patients will be accepted and examined free at the department's diagnostic laboratories in Chicago. Specimens taken from patients able to pay for such service should be sent to privately operated pathologic laboratories. Physicians and dentists who use this service are urged to select the specimens for biopsy with great care. The specimen should be large enough to include the lesion and also, if possible, a small part of adjacent normal tissue. It should be removed without crushing, placed immediately into a 10 per cent solution of formaldehyde and mailed in a tightly sealed container to the Cancer Diagnostic Service, State Department of Public Health, 1800 West Fillmore Street, Chicago. These specimens should be taken only when there are reasonable grounds for suspecting tumors. Reports of examinations will be placed in the mails usually within forty-eight hours after receipt of specimens. While this service is now limited practically to the laboratory examination of specimens submitted, it is anticipated that later the service can provide a source of material for those interested in tumor pathology and will serve as a medium for the exchange of impartial and friendly views on the diagnosis of tumor material. Dentists and oral surgeons are also invited to use the service. The diagnostic service will work in cooperation with the recently established division of cancer control, the work of which is educational in character. With Dr. Perry J. Melnick in charge, the cancer diagnostic service is a unit in the division of laboratories. Dr. Raymond V. Brokaw is chief of the division of cancer control, an administrative unit of the state department of public health.

Chicago

Society News.—The North Side Branch of the Chicago Medical Society will be addressed, October 3, by Dr. Elliott C. Cutler, Boston, on "The Art of Surgery."

University News.—Charles W. Patterson, Ph.C., registrar of Northwestern University Medical School for twenty-seven years, has been retired with the title associate professor emeritus of pharmacology. He had been associated with the school for forty-seven years.—The medical department of the University of Chicago eventually will receive all of the estimated \$100,000 estate of the late William S. Oppenheim. Under a trust established by the will, the income will go to relatives during their lifetime. The entire residuary estate is left to the university.

IOWA

Personal.—Dr. Albert J. Entringer, in charge of the Dubuque health department, has been appointed a member of the faculty of Loras College, effective September 1; he will lecture on health and hygiene to freshman students.—Dr. Thomas P. Bond, Des Moines, was recently granted life membership in the Polk County Medical Society; he has been a life member of the state medical society for the past three years.—Dr. Harry H. Ennis, LeMars, formerly medical director of district number 1, has been placed in charge of the Northeastern Iowa health unit with offices in Decorah.

Infantile Paralysis in Iowa.—The peak is believed to have been reached in the spread of poliomyelitis in Iowa, newspapers reported September 21. Of 400 cases reported since last spring, 176 were recorded in August and 200 up to September 21. It was estimated that at the time of this report 350 cases were still active. According to the newspapers, the disease was spread fairly evenly over the state, eighty of the ninety-nine counties having one or more cases. However, there were a few definite centers, the city of Waterloo being the hardest hit. Other concentrations were at Sioux City and in the counties of Appanoose and Bremer. All public social activities in Waterloo have been discouraged for several weeks. The opening of the schools was delayed three weeks but was expected to take place September 23. Children were refused admission to theaters, and such gathering places as swimming pools and clubs were closed.

Postgraduate Programs in Des Moines.—The Polk County Medical Society opened a series of postgraduate programs in Des Moines, September 18, with Drs. James T. Priestley, Rochester, Minn., and Clifford J. Barborka, Chicago, as the speakers. Their subjects were, respectively, acute conditions of the abdomen and "Food in the Practice of Medicine." Subsequent programs will be:

October 16: Drs. Addison W. Brown and Lindsay J. Ervin, Des Moines, Carcinoma of the Cervix and Drip Method in Treatment of Syphilis, respectively.

November 20: Drs. James Barrett Brown, St. Louis, and Andrew C. Ivy, Chicago, Traumatic Surgery and Relation of Physiology to Modern Medicine, respectively.

December 18: Dr. Julius S. Weingart, Des Moines, A Short Pathologic Conference.

March 19: Drs. David P. Barr, St. Louis, and George E. Shambaugh Jr., Chicago, The Making of a Diagnosis of Head Infections in Relation to General Practice, respectively.

February 19: Drs. Howard D. Gray, Avoidable Errors in Technique in Surgery of the Female Pelvis; Clifford W. Losh, Some Practical Points of Urology for the General Practitioner; Walter D. Abbott, Surgical Treatment of Intractable Pain, and Dwight C. Wirtz, Treatment of Tendon Injuries. All are of Des Moines.

May 21: Drs. Elmer L. Sevringhaus, Madison, Wis., and Eugene M. Kelling, Chicago, Endocrinology in General Practice and New Drugs, respectively.

April 16: Drs. Richard F. Birge, Des Moines, and Franklin E. Walton, St. Louis, Symposium on the Thyroid.

LOUISIANA

New Professor of Ophthalmology.—Dr. William Burton Clark, associate professor of ophthalmology, Tulane University of Louisiana School of Medicine, New Orleans, has been appointed professor, effective September 1. He succeeds Dr. Wiley R. Buffington, who has retired to devote his full time to private practice. Dr. Clark graduated at Emory University School of Medicine, Atlanta, Ga., in 1927 and has been associated with the faculty at Tulane since 1933.

Personal.—Dr. Edgar Galloway, Vivian, has been chosen superintendent of the Charity Hospital, Shreveport, succeeding Dr. Edgar L. Sanderson, who held the position for twelve years.—Dr. Marion H. Foster, Alexandria, has been appointed superintendent of the Huey P. Long State Charity Hospital, Pineville, succeeding Dr. Osmyn W. McFarland, resigned.—Dr. Edgar Hull, clinical professor and head of the department of medicine, Louisiana State University Medical Center, New Orleans, has been granted a leave of absence from October 15 to May 15 of next year to accept a temporary appointment as associate professor of medicine at Yale University School of Medicine, New Haven.

MARYLAND

Changes in Health Officers.—Dr. Josiah S. Bowen, head of the Baltimore County Health Department for twenty-six years, has resigned, newspapers reported recently. Dr. William H. F. Warthen, assistant health commissioner of Baltimore for the past six years, has been appointed to succeed Dr. Bowen.—Dr. Ralph F. Sikes, formerly with the Connecticut state health department, has been appointed senior medical supervisor in the bureau of venereal diseases in the Baltimore City Health Department.

MASSACHUSETTS

Dr. Packard Named Director of Biological Laboratory.—Charles Packard, Ph.D., of the Institute of Cancer Research, Columbia University, New York, has been appointed director of the Marine Biological Laboratory, Woods Hole. He had been assistant director since 1938 and previously had been clerk of the corporation for seven years. Dr. Packard has been at the Institute of Cancer Research since 1924. He took his doctorate in philosophy at Columbia in 1914.

Institute on Science and Food.—Wellesley College, Wellesley, will hold an institute on science and the nation's food, October 24-26, to bring together nationally recognized experts for discussion, to give undergraduates a sense of "the social outreach of their laboratory discipline" and to emphasize the role of the college as an "agency of scientifically implemented culture" working to advance the common good. The departments of botany, chemistry, economics, geography, hygiene and physiology are cooperating under the direction of Ruth Johnston, Ph.D., of the chemistry faculty.

MICHIGAN

Changes in Health Officers.—Dr. Richard Sears, Fremont, director of the tri-county health unit composed of Newaygo, Oceana and Lake counties since October 1938, has been named director of the Muskegon County health department, succeeding Dr. Reuben J. Harrington.

Appointments at Wayne.—Dr. Carl C. Pfeiffer, formerly of Chicago, has been placed in charge of a new branch of toxicology and will supervise the pharmacodynamic work in the Wayne University College of Pharmacy, Detroit. Paul S. Larson, Ph.D., formerly instructor in physiology at Georgetown University School of Medicine, Washington, D. C., has been appointed lecturer in the department of pharmacology. Dr. Pfeiffer graduated at the Department of Medicine, University of Chicago, in 1937. Dr. Larson received his degree as doctor of philosophy at the University of California in 1934.

Infantile Paralysis.—Fifty-eight counties in Michigan have reported cases of poliomyelitis in September, recording a total of 200 more than for the same period in 1939, according to a release from the state department of health, September 23. Accounting for 298 cases, twenty-four counties reporting five or more cases of the disease through September 18 are: Alger ten, Allegan five, Barry thirteen, Berrien seven, Branch nine, Calhoun eight, Delta ten, Dickinson thirteen, Eaton five, Gogebic seven, Ingham twenty-nine, Iron ten, Kalamazoo fourteen, Kent forty-three, Lapeer thirty-one, Mackinac five, Mecosta five, Midland six, Muskegon eight, Ottawa five, St. Joseph eight, Van Buren eleven, Washtenaw five and Wayne thirty-one. Sixty cases had been reported in September to the time of this report in thirty-four other counties.

New President and Director of Kellogg Foundation.—George B. Darling, Dr.P.H., associate director, and Emory W. Morris, D.D.S., associate executive director of the W. K. Kellogg Foundation, Battle Creek, were elected president and general director, respectively, August 19, succeeding the late Dr. Stuart Pritchard, who held both positions. Dr. Darling and Dr. Morris have been associated with the foundation for many years. Both received their degrees at the University of Michigan. The foundation has announced that it would spend \$2,553,650 in the coming year to further the health and well-being of children. All but \$634,000 will be spent in the counties of Calhoun, Allegan, Van Buren, Barry, Branch, Eaton and Hillsdale, where the foundation conducts community health projects. The \$634,000 will be expended as grants to various institutions.

MINNESOTA

Personal.—Dr. Richard B. Girvin has been appointed Minneapolis medical examiner for the Civil Aeronautics Authority, succeeding Dr. Albert J. Herbolzheimer, who has gone to Washington, D. C., with the authority. —Dr. Marcus H. Flintner, head of the Cass Lake Indian Hospital, Cass Lake, has been transferred to Arizona, where he will be in charge of an Indian tuberculosis sanatorium at Phoenix, according to *Minnesota Medicine*.

NEW JERSEY

Personal.—Robert P. Fischelis, Ph.D., secretary and chief chemist of the Board of Pharmacy of the State of New Jersey, has been appointed a member of the American Council on Pharmaceutical Education as one of three representatives of the American Pharmaceutical Association. The council is the accrediting agency for colleges of pharmacy. Dr. Fischelis will serve six years.

Society News.—Dr. James T. Rugh, Philadelphia, addressed the Gloucester County Medical Society, Woodbury, September 19, on "Low Back Pain—Causes and Treatment." —Dr. Arthur C. DeGraff, New York, will address a stated meeting of the Academy of Medicine of Northern New Jersey, Newark, October 17, on "The Present Status of Digitalis Therapy." —Dr. Frank W. Konzelmann, Philadelphia, addressed the Atlantic County Medical Society, Atlantic City, September 13, on "Biochemistry of Disease." —Dr. Jay Arthur Myers, Minneapolis, will address the Bergen County Medical Society, October 8, at Bergen Pines, on "Follow-Up Work in Tuberculin Testing Surveys."

NEW YORK

District Meetings.—The Fifth District Branch of the Medical Society of the State of New York held its annual meeting at Little Falls, September 24, with the following program:

Dr. Harry Dan Vickers, Little Falls, Newer Concepts of Hypertension.
Dr. George G. Ornstein, New York, Diagnosis of Carcinoma of the Lung.

Dr. Brewster C. Doust, Syracuse, Appendicitis in Children.

Dr. John C. A. Gerster, New York, General and Local Cryotherapy.

Dr. Henry Van Zile Hyde, Syracuse, Chemotherapy.

The Seventh District Branch held its annual meeting at the Clifton Springs Sanitarium, Clifton Springs, September 26. Drs. Herbert F. Dyer, Hamilton, Ont., and Elmer Milch, Buffalo, spoke on "Recognition and Prevention of the Late Toxemias of Pregnancy in Their Incipient Stages" and "Treatment of General Peritonitis Following Ruptured Appendix" respectively. The following officers of the state society made brief talks: Drs. James M. Flynn, Rochester, president; Peter Irving, New York, secretary; Joseph S. Lawrence, Albany, executive officer, and Mr. Dwight Anderson, New York, publicity director. A medical "correct or incorrect" contest was held, with Dr. Floyd S. Winslow, Rochester, as master of ceremonies.

New York City

Personal.—Dr. Russell L. Cecil has been made an honorary member of the Argentine League Against Rheumatism, according to *New York Medical Week*. —Dr. Israel S. Wechsler was appointed a member of the medical board of Hadassah, the Women's Zionist Organization of America, in addition to those reported in *THE JOURNAL*, August 3, page 395.

Tuberculosis Conference.—The Tuberculosis Sanatorium Conference of Metropolitan New York will hold a clinical session at Cornell University Medical College, October 9. The speakers will be Drs. Samuel Cohen, Jersey City, on lymphohematogenous tuberculosis and Oscar Auerbach, Staten Island, extrapulmonary tuberculosis. Dr. Mather Cleveland will present a discussion of "Joint Tuberculosis" and Dr. Howard S. Jeck, "Genito-Urinary Tuberculosis." Dr. Grant Thorburn will preside.

Friday Afternoon Lectures in Brooklyn.—The Medical Society of the County of Kings and Academy of Medicine of Brooklyn will open their series of Friday afternoon lectures October 4, with Dr. A. Benson Cannon as the speaker on "Diagnostic and Therapeutic Aspects of Dermatological Diseases." Other speakers for October will be:

Dr. George G. Ornstein, Clinical Aspects and Recent Contributions to the Treatment of Pulmonary Tuberculosis, October 11.

Dr. James M. Tarsy, Regional and Local Analgesic Injections for Local and Intractable Pain, October 18.

Dr. Samuel L. Siegler, Diagnostic and Therapeutic Aspects of Sterility, October 25.

NORTH CAROLINA

Diseases of Metabolism and of Blood-Forming Organs.—Duke University School of Medicine and Duke Hospital, Durham, will present a symposium, October 31 to November 2, on diseases of metabolism and of the blood-forming organs. The speakers will be:

Dr. Cyrus C. Sturgis, Ann Arbor, Mich., Hemorrhagic Diseases.

Dr. Louis K. Diamond, Boston, Practical Aspects of Treatment of Anemias in Childhood.

Dr. Claude E. Forkner, New York, The Leukemias.

Dr. Elliott P. Joslin, Boston, Diabetes and Its Treatment.

Dr. Thomas B. Cooley, Detroit, Hemolytic Anemias.

Dr. Fuller Albright, Boston, The Diagnosis of Hyperparathyroidism.

Dr. Eugene F. DuBois, New York, Clinical Application and Interpretation of the Basal Metabolic Rate.

Dr. Frank H. Lahey, Boston, President-Elect of the American Medical Association, Management of Hyperthyroidism; also A Practical Discussion of Surgical Diseases of the Thyroid Exclusive of Hyperthyroidism.

Dr. Allen O. Whipple, New York, Indications for and Results Following Splenectomy.

Dr. Leland S. McKittrick, Boston, Surgical Complications of Diabetes.

Dr. George R. Minot, Boston, Some Aspects of the Etiology, Diagnosis and Treatment of Iron Deficiency Anemia and Pernicious Anemia.

Dr. Frank A. Evans, Pittsburgh, The Nature of Obesity, Its Prevention and Cure.

Dr. Alexis F. Hartmann, St. Louis, The Complete Treatment of Diabetes Acidosis.

Dr. Russell M. Wilder, Rochester, Minn., What Is Hyperinsulinism?

OHIO

Personal.—Dr. Francis E. Mahla, Marion, has been appointed health officer of Sandusky and Erie County to succeed the late Dr. Frederick M. Houghtaling. Dr. Mahla was formerly assistant state health director.—Dr. Earl C. Van Horn, Oxford, has been appointed medical superintendent of the Ohio Masonic Home, Springfield.—Dr. Harry A. Neiswander, Pandora, has been appointed health commissioner of Putnam County, succeeding Dr. Louis M. Piatt, Ottawa, resigned.—Dr. Otto K. Engelke, West Union, has resigned as health officer of Adams County to join the Kellogg Foundation, Battle Creek, Mich.—Dr. Jonas L. Hurst, Dorset, has resigned as health officer of Ashtabula County.

Society News.—The semiannual meeting of the Ohio State Hospital Physicians' Association will be held at Longview State Hospital, Cincinnati, October 3-4. Among the speakers will be Drs. Douglas Goldman, Cincinnati, on "Electric Shock Therapy" and George H. Cook and John A. Dole Jr., Gallipolis, "Benzedrine Sulfate in Treatment of Epilepsy." Dr. Tom Douglas Spies, Cincinnati, will open a symposium on vitamin deficiencies and Dr. David A. Boyd Jr., professor of psychiatry, Indiana University School of Medicine, Indianapolis, will be the guest speaker at a banquet Thursday evening.—Dr. Theodore P. Eberhard, medical director of the Ellis Fischel State Cancer Hospital, Columbia, Mo., addressed the Summit County Medical Society, Akron, September 3, on "Certain Phases of the Cancer Problem."—Dr. Edgar V. Allen, Rochester, Minn., will address the Mahoning County Medical Society, Youngstown, October 22, on "Peripheral Circulation."

OKLAHOMA

Personal.—Dr. Woodrow L. Pickhardt, formerly of Chicago, has been appointed health officer of a new unit in Creek County with headquarters in Sapulpa.—Dr. Howe K. Riddle, Coweta, has been appointed health officer of Wagoner County, succeeding Dr. Walter R. Joblin, Porter.

Society News.—Dr. Ferdinand C. Helwig, Kansas City, Mo., addressed the Tulsa County Medical Society, Tulsa, September 23, on "Clinical and Experimental Studies of Coronary Disease with Special Emphasis on Trauma."—Drs. Carl S. McMurray, Nashville, Tenn., and Wam Langston, Oklahoma City, addressed the Southern Oklahoma Medical Association in Shawnee, September 26, on "Endocrine Considerations in Gynecology" and "Blood Dyscrasias" respectively.—Dr. Paul C. Gallaher, Shawnee, addressed the Pottawatomie County Medical Society, Shawnee, July 20, on rheumatic fever.

Annual Fall Clinical Conference.—The tenth annual fall clinical conference of the Oklahoma City Clinical Society will be held in Oklahoma City, October 28-31, at the Biltmore Hotel. Postgraduate courses, general assemblies, round table luncheons and evening symposiums will make up the program. Dr. Nathan B. Van Etten, New York, President of the American Medical Association, will be a special guest, and scientific speakers will include:

Dr. William B. Carrell, professor of orthopedic surgery, Baylor University College of Medicine, Dallas, Texas.

Dr. Robert J. Crossen, assistant professor of clinical obstetrics and gynecology, Washington University School of Medicine, St. Louis.

Dr. Elliott P. Joslin, clinical professor of medicine emeritus, Harvard Medical School, Boston.

Dr. Norman M. Keith, professor of medicine, University of Minnesota Graduate School, Rochester.

Dr. Joseph Earle Moore, associate in medicine, Johns Hopkins University School of Medicine, Baltimore.

Dr. Edmund H. Spaeth, associate professor of ophthalmology, University of Pennsylvania Graduate School of Medicine, Philadelphia.

Dr. A. Elmer Belt, associate professor of urology, College of Medical Evangelists, Los Angeles.

Dr. Morris Edward Davis, associate professor of obstetrics and gynecology, University of Chicago School of Medicine.

Information concerning the conference may be obtained by addressing the secretary, 512 Medical Arts Building, Oklahoma City.

OREGON

Personal.—Dr. Joseph F. Wood, Portland, has resigned as secretary of the state board of medical examiners and from membership on the board. Dr. Linford S. Besson, Portland, is acting secretary.—Dr. Keith P. Russell, Portland, has been appointed director of the division of communicable disease control in the city department of health.

Counties Sponsor Postgraduate Course.—The postgraduate committee of the Polk-Yamhill-Marion Counties Medical Society will sponsor a postgraduate symposium on gastrointestinal diseases by the following members of the faculty of

the University of California Medical School, San Francisco: Drs. Montague S. Woolf, Felix Cunha and Fred H. Kruse. The meetings will be in Salem, October 10-11. There will be a registration fee of \$5.

PENNSYLVANIA

Society News.—Dr. Carl J. Wiggers, Cleveland, addressed the Washington County Medical Society, Washington, September 11, on "The Problem of Ventricular Fibrillation and Cardiac Resuscitation."—Drs. Henry T. Price and Theodore O. Elterich, Pittsburgh, addressed the Westmoreland County Medical Society, Greensburg, September 17, on "Care of the Newborn" and "Convulsions in Childhood" respectively.—Dr. Eldridge L. Eliason, Philadelphia, addressed the Cambria County Medical Society, Johnstown, September 12, on "The Patient and His Fracture."—Dr. Harvey G. Beck, Baltimore, addressed the Lawrence County Medical Society, New Castle, September 5, on "Chronic Illness Resulting from Carbon Monoxide."

GENERAL

Airplane Accidents.—The *Statistical Bulletin* of the Metropolitan Life Insurance Company in its August issue reports that in 1938 deaths resulting from all types of aviation activities, civil and military, numbered 436. Fatalities of this kind were 214 in 1927, 473 in 1928 and 596 in 1930. A decline took place in 1931 to 490 deaths. It is pointed out that one reason why the expected rise in fatalities did not materialize is that the anticipated increase in operation of privately owned planes did not take place.

Association for Advancement of Oral Diagnosis.—The American Association for the Advancement of Oral Diagnosis, established in 1938, will hold its annual meeting at the New York Academy of Medicine, October 17-18, during the annual Graduate Fortnight of the Academy. The purposes of this organization are to correlate oral diagnosis in dentistry and medicine, to encourage the biological, scientific and professional aspects of dentistry, and to foster cooperative research. Physicians and dentists of the organized medical and dental professions who are members in good standing in their respective organizations in the counties in which they practice are eligible for membership. Information may be obtained from H. Justin Ross, D.D.S., 515 Madison Avenue, New York.

Association of Military Surgeons.—The forty-eighth annual meeting of the Association of Military Surgeons of the United States will be held at the Hotel Statler, Cleveland, October 10-12, under the presidency of Major Gen. Charles R. Reynolds, U. S. Army, Ret. Among the speakers will be:

Rear Admiral Ross T. McIntire, Surgeon General, U. S. Navy, Selection of Men Adapted for Special Fields.

Dr. Crawford N. Baganz, Lyons, N. J., So-Called Shell Shock: Types, Etiology and Means for Its Prevention.

Dr. Russell L. Haden, Cleveland, Chemotherapeutic Developments Since the Last War.

Capt. Douglas B. Kendrick Jr., M.C., U. S. Army, Washington, D. C., Preparation, Supply, Distribution and Use of Blood Plasma in Military Service as Determined by the Committee Working with the Research Committee of the National Defense Council.

Drs. Ernest P. McCullagh and George Crite, Cleveland, Differential Diagnosis of Neurocirculatory Asthenia (Soldier's Heart) and Results in 152 Denervations of the Adrenal Glands in Treatment of Neurocirculatory Asthenia.

Lieut. Albert R. Belmke, U. S. Navy, Washington, D. C., Submarine Problems.

Dr. Gustavus M. Blech, Chicago, Surgical Technic in Modern Battle.

Brig. Gen. Frank T. Hines, Administrator of Veterans' Affairs, Washington, D. C., The Veterans' Administration and National Defense.

Committee Studies Antimalarials.—A committee on chemotherapy appointed by the National Research Council to stimulate research on new and useful synthetic drugs has begun its work with antimalarials as its first assignment. The committee was formed as a permanent organization after the group, appointed on a temporary basis by the division of chemistry and chemical technology, had made a preliminary survey of the field of malaria and antimalarials. Its original objective was the study of malaria, in view of the possibility that the supply of quinine from Java may be cut off and because the synthetic drugs are more expensive than many can afford, it was said. After the survey it was felt that the committee should concern itself not solely with antimalarials but should have as its function chemistry in the service of medicine. The broader field will permit the committee to offer its services to combat other diseases as well. The chairman of the committee is Marston T. Bogert, Ph.D., professor emeritus of organic chemistry at Columbia University, and the members are Lyndon F. Small, Ph.D., of the National Institute of Health, Washington, D. C.; Leonard H. Cretcher, Ph.D., assistant director of Mellon Institute, Pittsburgh; Dr.

Lowell T. Coggeshall, of the International Health Division of the Rockefeller Foundation, New York, and Dr. Torald H. Sollmann, dean, Western Reserve University School of Medicine, Cleveland. The committee has as one of its objects a closer cooperation between pharmacologists and chemists. It plans to function as a clearing house for information as to the chemists, manufacturers, pharmacologists and others now at work in the field, the special lines of investigation they are following and any other pertinent data. Preparation of a compact semipopular presentation of the malaria situation throughout the world, and particularly in this country, including a summary of what is being done here and how it is being handicapped and retarded by lack of funds, is another plan. Funds will be sought to support the committee's work, to establish research fellowships and to finance other activities that will advance achievement of its objects. Finally, the committee asks that individuals, organizations, institutions and manufacturers who are willing to cooperate communicate with Dr. Bogert at Havemeyer Hall, Columbia University, New York.

Pan American Congress of Ophthalmology.—The first Pan American Congress of Ophthalmology, sponsored by the American Academy of Ophthalmology and Otolaryngology, will be held in Cleveland, October 11-12, immediately after the annual meeting of the Academy. Among speakers announced for the program are:

Dr. Manuel U. Troncoso, New York, The Value of Gonio-copy in the Prognosis and Treatment of Glaucoma.

Dr. Manuel Marquez y Rodriguez, Mexico City, The Best and Most Exact Method for Diagnosis of Slight Astigmatism by Means of Bicylindrical Combinations.

Dr. Genseric G. Jayme, Annapolis, Brazil, Cephalic Tetanus of Ocular Origin.

Dr. Pereira Gomes, São Paulo, Brazil, Tumors of the Optic Nerve.

Dr. Tomas R. Yanes, Habana, Cuba, Dacryocystorhinostomy.

Dr. Carlos Charlin, Santiago, Chile, Occult Tuberculosis of the Eye.

Dr. William L. Benedict, Rochester, Minn., Orbital Hyperostosis.

Dr. Daniel B. Kirby, New York, Congenital Bilateral Colobomata of the Upper and Lower Eyelids: Plastic Surgical Correction.

Drs. Alan C. Woods and Jack S. Guyton, Baltimore, Chemotherapy in Ophthalmology.

Dr. Samuel Hanford McKee, Montreal, Canada, Observations on the Fundus Oculi in Diabetes Mellitus.

It is expected that the Pan American congress will be placed on a permanent basis during this meeting. The committee that has arranged the first congress is made up of Drs. Harry S. Gradle, Chicago; Conrad Berens, New York, and Moacyr E. Alvaro, São Paulo, Brazil.

CANADA

Personal.—Dr. Charles W. MacMillan, St. John, has been appointed chief medical officer for the province of New Brunswick.—Dr. George F. Stephens, superintendent of the Winnipeg General Hospital, Winnipeg, Man., for twenty-one years, has been appointed superintendent of the Royal Victoria Hospital, Montreal.

FOREIGN

Hospital Equipment for China.—A fund contributed by the Committee for Medical Aid to China in Victoria, B. C., Canada, has been used to establish a library in connection with the medical school at Yenan and to purchase an x-ray machine for the Kuomaio Model Hospital in memory of Dr. Norman Bethune, Canadian surgeon who went to China in 1937. Dr. Bethune died Nov. 13, 1939, of septicemia following an injury received while operating. In addition to working with the wounded immediately behind the lines, Dr. Bethune organized the International Peace Hospitals, which now include four base hospitals, a transport network for supplies and mobile medical teams. The library will be an invaluable aid to medical students who have been studying with roughly duplicated notes and an almost total lack of reference material, according to the China Defense League *Newsletter*. The hospitals are in urgent need of surgical instruments and equipment, including many types of forceps, scissors, Luer syringes, hypodermic needles and various kinds of rubber tubes.

CORRECTION

Health Department Headquarters Remain in Sacramento.—The director of the state department of public health of California, Dr. Bertram P. Brown, writes that headquarters of the department will remain in Sacramento with branch offices in Los Angeles and San Francisco as heretofore. An announcement that the headquarters of the department had been moved to Los Angeles, published in *THE JOURNAL*, September 7, page 867, was based on reports appearing in the newspapers.

LONDON

(From Our Regular Correspondent)

Aug. 17, 1940.

Hysterical Contractures Following War Injuries

At the Royal Society of Medicine Sir Arthur Hurst opened a discussion on hysterical contractures following war injuries. In civil life contractures following injuries were comparatively rare but after war injuries were frequent. During the last war the nature of these contractures was much discussed but only toward the end did it become almost universally recognized that they were hysterical and could be quickly cured by proper treatment. The most common contracture followed injury to the soft parts of any type. Sometimes there was no wound, only a twist or a sprain. A limb was sometimes found completely stiff after amputation of a hammer toe or removal of a semilunar cartilage, but this was amenable to psychotherapy. The postures were of great variety. The commonest developed in the hand and were of two main kinds: with the fingers stiffened in extension or tightly flexed into the palm. One patient's hand was contracted for two and one-half years and, when cured at a single sitting and the hand was opened, the nails had grown deeply into the palm. Fixation of the wrist was infrequent; of the elbow, frequent; of the shoulder held tightly to the side, occasional. In a number of cases the toes were affected and the patient walked on the ball of the foot. The knee and the hip were often fixed. Immediately after the injury the patient adopted the most comfortable position and this might develop into a contraction. In some cases the limb was put into a splint and after its removal maintained the same position. The limb was fixed because the patient had lost the idea of movement. This could be prevented by putting the limb through complete movements when dressings were removed. Contractures were most likely when the patient was sent to the physical therapy department. Babinski made the mistake of concluding that contractures were reflex and therefore organic in origin and not hysterical. What led him to this was the remarkable trophic changes in patients with deficient circulation following disuse of a part. The skin became wrinkled, blue, thin and shiny and the finger nails gray and lusterless, grooved and brittle; the bones showed abnormal translucency. But all these changes, simulating the trophic changes following nerve injury, were simply the result of disuse and deficient circulation.

Treatment in the early days of the war consisted in a certain amount of suggestion and occasional hypnosis, but later Hurst and his colleagues found simpler methods of psychotherapy more valuable. The patients were not commonly hysterical and never had had "shell shock." Persuasion, manipulation and reeducation were found effective and the ideal patient was cured merely by telling him what to do. It was explained to him how the contracture developed, that it was necessary to rest the limb after the injury, but that when the splint and bandage were taken away the limb should be moved. The patient was taught to relax the limb, and the physician moved the affected part a little and allowed it to relax again.

In the discussion Dr. J. B. Mennell (physical therapist) said that if there was one condition more than another with which the physical therapist should not interfere it was these contractures. Unraveling them by force was a barbarous method and the contractures recurred. Colonel Henry Yellowlees (psychiatrist) did not find Hurst's one remark about the psychopathology—that the patient lost the idea of movement—satisfying. Hurst replied that the important thing was to get results. He believed that, if he ranged the ten medical officers who worked under him in order of their success, the one who would be last

or nearly last was the skilled psychotherapist. The worst cases of shell shock seen after the war of 1914-1918 were those which had been under the care of psychologists in France, who had carried out experiments in hypnotism with disastrous results. The president (Mr. Zachary Cope) remarked that Sir Arthur Hurst had stated that in some cases the joints could not be moved even under general anesthesia. Surely under deep anesthesia a joint not absolutely ankylosed would be movable. Hurst replied that he had seen a soldier whose knees were rigidly extended. He had had many spa treatments without improvement. Under a general anesthetic he did not relax, but under psychotherapy relaxation was gradually obtained. It was extremely difficult to explain such cases.

The Improvement of Bread

The Medical Research Council has issued a statement on the advantages of bread made from flour of higher extraction than that now in use. Flour should contain the germ of the wheat, as much as possible of the aleuron layer, and the finer portions of bran. Instead of consisting of about 70 per cent of the wheat grain, as at present, flour should contain from 80 to 85 per cent. The content of certain vitamins, all minerals and fat would thus be improved. This improvement would benefit most persons of small income whose power to purchase protective foods is limited. The minimum daily requirement of vitamin B₁ is from 300 to 500 international units. The pound loaf made from white flour of 70 per cent extraction gives from 80 to 160 units; from flour of 80 to 85 per cent extraction from 300 to 450 units, almost the total requirement. The Accessory Food Factors Committee of the Lister Institute and the Medical Research Council examined the ways in which the health of the people might be benefited by improving the value of wheaten bread and concluded that this change in one dietary essential alone would benefit greatly the health of children and adults of all classes. There would also be benefit from increase of other members of the B complex, such as riboflavin, and of vitamin E. The carotene (provitamin A) content would also be improved, if not previously destroyed by bleaching. The committee therefore condemns the bleaching of flour by oxidizing agents, such as nitrogen chloride and nitrogen peroxide. Increased fat content would be another benefit.

The total mineral content would be doubled. The daily requirement of iron may be taken as 10 mg. The pound loaf of 70 per cent extraction supplies only 5 mg. Anemia from iron deficiency is common among poorer women, especially in pregnancy, and among their infants. The daily requirement of calcium may be taken as 500 mg. The pound loaf of 70 per cent extraction contains less than 150 mg. Insufficiency of calcium is an important defect in the British diet but would not be compensated by increased extraction of flour. Bread is a poor source of calcium. The foods most rich in calcium are milk, cheese and green vegetables.

There are possible disadvantages from the increased extraction of flour. Flours of high extraction, if coarsely ground, are slightly less utilized than finer flour. For this reason 80 to 85 per cent extraction is recommended; it represents a fraction of the wheat grain in which improvement in the nutritive value of the flour is pronounced but in which decreased utilization has scarcely begun. But if a flour of 90 or even 100 per cent extraction could be obtained in finely ground condition, the nutritive advantages would be increased and the disadvantages of incomplete utilization would tend to disappear. Phytic acid precipitates calcium, so that it cannot be absorbed. Although high extraction flour contributes more calcium to the diet, it also contributes more phytic acid. Because of the need of more calcium in the British diet and its deficiency in bread, whatever the degree of extraction of the flour, the committee recommends the addition of calcium salts to bread, while at the same

time the foods rich in calcium should be promoted. The committee condemns the use of alkaline baking powder because it destroys the vitamin B₁ content of bread.

Provision for the Treatment of Air Raid Casualties

Speaking at a luncheon of the National Defense Public Interest Committee Mr. Malcolm MacDonald, minister of health, stated that there were now 1,800 fixed first aid posts in England and Wales, 800 mobile first aid posts, 14,000 ambulances and 15,000 ordinary cars waiting to carry sitting patients. The staff of the first aid section numbered about 100,000 persons. The Ministry of Health was also responsible for the treatment of all cases resulting from enemy action and for the hospital treatment of all but a small number of military casualties on any battle front in this country or outside. The organization passed its preliminary test at the time of the evacuation of Dunkirk, and the medical staff was astonished at the rapidity with which the patients recovered. That confirmed the high physical quality of our men and was also partly due, no doubt, to the excellent modern nursing and doctoring.

PLASMA TRANSFUSION ADOPTED

The recent suggestion to substitute for transfusion of whole blood plasma transfusion, because it is equally effective in cases of shock and is attended with less risk of reactions, has been adopted with good results. Mr. MacDonald stated that the plasma would keep indefinitely and so the call on blood donors had been reduced. But a further advance had been made. Plasma stored in bottles was not easily transportable. So by evaporation it was reduced to a white powder, by the addition of water to which the original liquid with all its properties could be reconstituted.

Marriages

RAYMOND LOUIS EVANS, Cincinnati, to Miss Augusta Dorrance Farnham of Wilkes-Barre, Pa., at Montrose, Pa., August 31.

DALE EMERSON BARBER, Oakland, Calif., to Miss Barbara Way of Washington, D. C., in San Francisco, August 24.

VICTOR R. KRUEGER, Bonduel, Wis., to Miss Blanche Lam-berton of Melrose, Minn., in Duluth, Minn., June 25.

THOMAS E. CANNING, Colville, Wash., to Miss Mary Lou Ralph of Spokane at Clark Ford, Idaho, August 3.

HENRY ANDREWS COTTON JR., Trenton, N. J., to Miss Anne Tooker at South Williamstown, Mass., August 31.

THEODORE SCHLOSSBACH, Ocean Grove, N. J., to Miss Eleanor Pegley Krause at Asbury Park, August 17.

SAMUEL BANCROFT FLUKE, Harrisburg, Pa., to Miss Florence Hardy of Washington, D. C., June 15.

VLADIMIR C. FLOWERS, Ithaca, N. Y., to Miss Alice Victoria Rex of Oak Park, Ill., August 31.

CLAUDE K. LINDLER to Miss Margaret Maxwell Ward, both of Columbia, S. C., August 24.

GEORGE M. KLITCH, Harrisburg, Pa., to Miss Ruthanna Mark of Hagerstown, Md., June 22.

JESSE J. HEATON, Tiffin, Ohio, to Miss Inez A. Johnson of McCutchenville, August 1.

JOSEPH DUDGEON WALKER to Mrs. Nannie Dunlap, both of Houston, Texas, July 25.

MARGARET PAXSON, Pottsville, Pa., to Mr. Harry F. Brian of Lancaster, August 17.

RAYMOND C. HACKER to Miss Florence A. Mease, both of Philadelphia, June 29.

LUDWIG J. O'BLAZNEY, Simpson, Pa., to Miss Wanda Faseski, August 31.

JAMES L. KING to Miss Helen Morrow, both of Florence, S. C., in August.

DONALD E. MORRISON, Penbrook, Pa., to Miss Alice Louise Gillan, June 12.

Deaths

Maude Elizabeth Seymour Abbott, Montreal, Que., Canada; University of Bishop College Faculty of Medicine, Montreal, 1894; honorary M.D., C.M., McGill University, 1910; formerly assistant professor of medical research and curator of the medical museum, McGill University Faculty of Medicine and lecturer of pathology from 1912 to 1923; was acting curator of the Canadian Army Medical Museum; professor of pathology and bacteriology at the Woman's Medical College of Pennsylvania, Philadelphia, from 1923 to 1925; member of the American Association of Anatomists and the American Association of Pathologists and Bacteriologists; permanent secretary-treasurer and one of the founders of the International Association of Medical Museums; editor of the *Journal of Technical Methods* and *Bulletin of the International Association of Medical Museums* from 1907 to 1938; managing editor of the "Osler Memorial Volume"; on the editorial board of the *Canadian Medical Association Journal*; author of "Classified Bibliography of Sir William Osler's Publications," "Atlas of Congenital Cardiac Disease" and "Historical Sketch of the Medical Faculty of McGill"; was awarded the degree of doctor of laws honoris causa from McGill University; aged 71; died, September 2, of cerebral hemorrhage.

Harold M. Hays ☉ New York; Columbia University College of Physicians and Surgeons, New York, 1905; instructor of otolaryngology at his alma mater from 1914 to 1922; associate professor of laryngology at the New York Polyclinic from 1914 to 1917; member of the American Academy of Ophthalmology and Otolaryngology and the American Laryngological, Rhinological and Otolological Society; fellow of the American College of Surgeons; past president of the American Federation of Organizations for the Hard of Hearing; founder, president and director of the New York League for the Hard of Hearing; served during the World War; director of the Hebrew Association for the Deaf; was president of the Association of Private Hospitals of Greater New York; medical director of the Park East Hospital and the Park West Hospital; consulting otologist to the Convalescent Home of Hebrew Children, Rockaway Park, and St. Joseph Hospital, Far Rockaway; consulting laryngologist to the Sing Sing Prison Hospital, Ossining; author of "Diseases of Nose, Throat and Ear" and "Modern Conception of Deafness"; aged 59; died, August 20, of coronary thrombosis.

Charles Francis Nassau ☉ Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1891; Jefferson Medical College of Philadelphia, 1906; clinical professor of surgery at the Jefferson Medical College; past president of the Philadelphia County Medical Society; honorary president of the John Chalmers Da Costa Foundation; fellow of the American College of Surgeons; formerly director of public health of Philadelphia; served during the World War; chief surgeon, Frankford Hospital; surgeon, St. Joseph's Hospital and Girard College; assistant surgeon, Jefferson Hospital; consulting surgeon, Mount Sinai Hospital, Kensington Hospital for Women and Rush Hospital for Consumption and Allied Diseases, Philadelphia, and the Pottstown (Pa.) Hospital; aged 71; died, August 11, in the Easton (Pa.) Hospital of coronary occlusion.

John Crean Cardwell, Brooklyn; University of the City of New York Medical Department, 1888; member of the Medical Society of the State of New York; instructor in physiology at Harvard Medical School, Boston, from 1891 to 1893; instructor in physiology at the Long Island College Hospital from 1900 to 1904, lecturer from 1904 to 1908, assistant professor from 1908 to 1910, adjunct professor 1910-1911, associate professor from 1911 to 1913, professor of physiology and acting professor of pharmacology from 1919 to 1928, professor of physiology and pharmacology from 1928 to 1930 and since 1932 emeritus professor; member of the American Association of Anatomists; aged 74; died, August 3.

Larkin Smith ☉ Nashville, Tenn.; University of Nashville Medical Department, 1888; Vanderbilt University School of Medicine, Nashville, 1889; demonstrator of histology, pathology and microscopy from 1889 to 1898, professor of hygiene and preventive medicine, associate professor of pathology from 1909 to 1915, instructor in medicine from 1915 to 1925 and instructor in clinical medicine from 1925 to 1928 at the Vanderbilt University School of Medicine; at one time secretary of the Tennessee State Medical Association; formerly health officer of Nashville; served during the World War; formerly on the staff of the Vanderbilt Hospital; aged 74; died, July 17, of pernicious anemia and diabetes mellitus.

James McKenty, Winnipeg, Man., Canada; Queen's University Faculty of Medicine, Kingston, Ont., 1890; served at various times as lecturer in anatomy, assistant professor in clinical medicine, associate professor of surgery and emeritus professor of surgery at the University of Manitoba Faculty of Medicine; was president of the Winnipeg Medical Society; fellow of the American College of Surgeons; for many years on the staffs of St. Boniface, Misericordia and St. Joseph's hospitals; aged 74; died, August 11, of cerebral hemorrhage.

Robert Kingman, Brooklyn; Long Island College Hospital, Brooklyn, 1899; formerly clinical instructor in neurology at his alma mater; past secretary and vice president of the Brooklyn Neurological Society; served as New York State Examiner in Lunacy, and New York State Examiner of Mental Defectives; was consulting neuropsychiatrist in the United States Public Health Service hospitals; on the staff of the Kings County Hospital and the Greenpoint Hospital; aged 64; died, August 7, of coronary thrombosis.

John Archer Hatchett, Oklahoma City; Missouri Medical College, St. Louis, 1884; member of the House of Delegates of the American Medical Association, 1905-1906, and Second Vice President in 1908; member of the Oklahoma State Medical Association; past president of the Oklahoma County Medical Society; professor emeritus of obstetrics at the University of Oklahoma School of Medicine; at one time on the staff of the University Hospital; aged 87; died, August 16, of arteriosclerosis and pneumonia.

Howard Leighton Updegraff ☉ Los Angeles; University of Nebraska College of Medicine, Omaha, 1919; fellow of the American College of Surgeons; honorary member of the Royal Australasian Medical Society; member of the Society of Plastic and Reconstructive Surgery; on the staffs of the Hollywood Presbyterian, Cedars of Lebanon, Orthopedic and Methodist hospitals; associate editor of the *American Journal of Surgery*; aged 43; died, August 8, of acute hemorrhagic pancreatitis.

Augustus Thorndike, Boston; Harvard Medical School, Boston, 1888; member of the Massachusetts Medical Society; past president of the American Orthopedic Association; formerly instructor of orthopedics at his alma mater; at one time assistant visiting surgeon to the House of the Good Samaritan and assistant surgeon to the Children's Hospital; author of "A Manual of Orthopedic Surgery," published in 1907; aged 77; died, August 23, in Bar Harbor, Maine, of heart disease.

Joseph Brock Harrison ☉ Westfield, N. J.; College of Physicians and Surgeons, medical department of Columbia College, New York, 1876; for many years member of the board of education and president of the board of health; past president of the Union County Medical Society; on the courtesy staff of the Muhlenberg Hospital, Plainfield, and the Elizabeth (N. J.) General Hospital; aged 88; died, August 25, of uremia, hypertrophy of the prostate and myocarditis.

Anson James Singer, East Stroudsburg, Pa.; University of the City of New York Medical Department, 1883; member of the Medical Society of the State of Pennsylvania; past president of the Monroe County Medical Society; was president of the board of trustees of the State Teachers College; one time mayor; formerly on the staff of the General Hospital of Monroe County; aged 82; died, July 29.

Walter Alonzo Bartlett, Manchester, N. H.; Dartmouth Medical School, Hanover, 1911; member of the New Hampshire Medical Society; formerly member of the board of education; on the staff of the Hillsborough County General Hospital, Grasmere, and the Sacred Heart Hospital; aged 50; died, August 12, in the New Hampshire State Sanatorium, Glencliff, of pulmonary tuberculosis.

William Henry Howell ☉ Altoona, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1899; fellow of the American College of Surgeons; past president of the Blair County Medical Society; on the staff of the Altoona Hospital and Mercy Hospital; aged 67; died, August 13, in the Annie M. Warner Hospital, Gettysburg, of cerebral hemorrhage.

Arthur Lloyd Chambers ☉ New York; New York Homeopathic Medical College and Flower Hospital, New York, 1914; associate professor of ophthalmology at his alma mater; fellow of the American College of Surgeons; on the staffs of the New York Ophthalmic Hospital, Flower and Fifth Avenue hospitals and the Metropolitan Hospital; aged 51; died, August 14.

Thomas Albert Sinclair, Houston, Texas; Keokuk Medical College, College of Physicians and Surgeons, Keokuk, Iowa, 1905; member of the State Medical Association of Texas; medical superintendent of the Heights Clinic-Hospital; aged 67;

member of the city health department from 1920 to 1928; died, July 26, of heart disease.

Henry LeBaron Peters ♂ Bridgeport, Conn.; McGill University Faculty of Medicine, Montreal, Que., Canada, 1907; for many years medical examiner of Bridgeport; attending physician and director of the pathologic and bacteriologic laboratory of the Bridgeport Hospital; aged 58; died in August of coronary thrombosis.

William Joseph Leonard, Provincetown, Mass.; College of Physicians and Surgeons, Baltimore, 1896; served during the World War; formerly police department surgeon and city physician of Springfield; at one time on the staffs of the Mercy Hospital and the City of Springfield Infirmary, Springfield; aged 70; died, July 25.

Bleeker James Knapp ♂ Evansville, Ind.; Rush Medical College, Chicago, 1901; member of the American Academy of Ophthalmology and Oto-Laryngology; fellow of the American College of Surgeons; aged 63; surgeon to the Protestant Deaconess Hospital, where he died, August 20, of chronic nephritis and uremia.

Ralph Harpel Dunlap, Bellevue, Pa.; Johns Hopkins University School of Medicine, Baltimore, 1919; member of the Medical Society of the State of Pennsylvania; on the staff of St. John's General Hospital, Pittsburgh, and the Salvation Army Woman's Home and Hospital; aged 48; died, August 8.

Maximilian Joseph Kern, St. Cloud, Minn.; John A. Creighton Medical College, Omaha, 1904; member of the Minnesota State Medical Association; for many years county coroner, and member of the city council; aged 59; died, August 10, of hypertension and cerebral hemorrhage.

Elisha C. Chew ♂ Atlantic City, N. J.; University of Pennsylvania Department of Medicine, Philadelphia, 1891; past president of the Atlantic County Medical Society; formerly police surgeon; on the staff of the Atlantic City Hospital; aged 73; died, August 5, of chronic fibroid phthisis.

Joseph Montgomery Casey, Fort Madison, Iowa; Rush Medical College, Chicago, 1888; member of the Iowa State Medical Society; aged 75; on the staff of the Sacred Heart Hospital and the Atchison, Topeka and Santa Fe Railway Hospital, where he died, July 30, of myocarditis.

Warren Bunting Shaner, Pottstown, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1882; member of the Medical Society of the State of Pennsylvania; for many years on the staff and secretary of the staff of the Pottstown Hospital; aged 80; died, July 15.

Edward H. White ♂ Cumberland, Md.; Baltimore Medical College, 1899; past president of the Allegany and Garrett Counties Medical Society; at one time city and county health officer; on the staffs of the Allegany and Memorial hospitals; aged 70; died, July 13.

Robert Edward Lee Thacker ♂ Lexington, Okla.; University of Louisville (Ky.) Medical Department, 1893; served during the World War; aged 74; died, July 10, in the Wesley Hospital, Oklahoma City, of hypertensive heart disease and prostatic hypertrophy.

William Wilberforce Farr, Philadelphia; University of Pennsylvania Department of Medicine, Philadelphia, 1887; served during the World War; aged 75; died, August 19, in the Germantown Dispensary and Hospital of bronchopneumonia and diabetes mellitus.

Napoleon Gustavus Gewinner, Macon, Ga.; Medical College of the State of South Carolina, Charleston, 1879; member of the Medical Association of Georgia; aged 82; died, August 19, in Atlanta of acute intestinal obstruction and mesenteric thrombosis.

Henry Grady Lassiter ♂ Weldon, N. C.; Jefferson Medical College of Philadelphia, 1918; past president of the Halifax County Medical Society; aged 48; died, August 1, in the Roanoke Rapids (N. C.) Hospital of cerebral hemorrhage and hypertension.

William Hugh Hamley, Lake Providence, La.; University of Tennessee College of Medicine, Memphis, 1914; member of the Louisiana State Medical Society; served during the World War; aged 51; died, August 6, in Vicksburg, Miss., of cirrhosis of the liver.

William Albert Jolley, North Little Rock, Ark.; Jefferson Medical College of Philadelphia, 1896; member of the American Psychiatric Association; served during the World War; on the staff of the Veterans Administration Facility; aged 68; died, August 2.

Arthur Clinton Hendrick, Toronto, Ont., Canada; University of Toronto Faculty of Medicine, 1900; fellow of the American College of Surgeons; on the staff of the Toronto General Hospital and the Grace Hospital; aged 66; died, August 1.

Willet W. Binion, Benevolence, Ga.; Atlanta Medical College, 1885; member of the Medical Association of Georgia; for many years member of the county board of education; aged 80; died, August 13, of chronic nephritis and arteriosclerosis.

William Henry Lehner, Brentwood, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1895; member of the Medical Society of the State of Pennsylvania; formerly on the staff of the Southside Hospital, Pittsburgh; aged 76; died, July 21.

Ellen Elizabeth Brown, Graterford, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1881; member of the Medical Society of the State of Pennsylvania; for many years on the staff of the Chester (Pa.) Hospital; aged 91; died, July 29.

Lawrence Alvies Mendonsa, St. Louis; St. Louis College of Physicians and Surgeons, 1906; member of the Missouri State Medical Association; secretary of St. Louis County Medical Society; aged 58; died, July 17, in the Central Hospital.

Jacob S. Thompson, Stephens, Ark.; University of Louisville (Ky.) Medical Department, 1882; past president of the Ouachita County Medical Society; at various times president of the school board and bank president; aged 83; died, July 10.

Friedrich Schiff, New York; Friedrich-Wilhelms-Universität Medizinische Fakultät, Berlin, Prussia, 1913; member of the Medical Society of the State of New York; bacteriologist on the staff of the Beth Israel Hospital; aged 51; died, July 30.

Job Thigpen Cater, Montgomery, Ala.; Rush Medical College, Chicago, 1930; member of the Medical Association of the State of Alabama and the Association for Research in Ophthalmology; aged 39; died, July 3, in the Hubbard Hospital.

Harry Douglas Thompson ♂ Beverly Hills, Calif.; College of Physicians and Surgeons, Los Angeles, 1918; on the staff of the Presbyterian Hospital-Olmsted Memorial, and chairman of the library committee; aged 48; died, July 3.

John Calvin Simon, Cleveland; Eclectic Medical Institute, Cincinnati, 1889; formerly county coroner; on the staff of the Grace Hospital and St. John's Hospital; aged 73; died, August 6, in Olmsted Falls, Ohio, of coronary occlusion.

Nicholas R. Engels, Chicago; Rush Medical College, Chicago, 1896; member of the Illinois State Medical Society; on the staff of St. Bernard's Hospital; aged 76; died, August 11, of cerebral hemorrhage and arteriosclerosis.

Alphonse Lagaci, Franklin, N. H.; M.B., School of Medicine and Surgery of Montreal, Faculty of Medicine of the University of Laval at Montreal, 1907, and M.D. in 1909; for many years mayor; aged 58; died, July 26.

James Garrity ♂ Chicago; Rush Medical College, Chicago, 1904; aged 60; for many years on the staff of the West Suburban Hospital, Oak Park, Ill., where he died, August 31, of injuries received in an automobile accident.

Lawrence Robert Harris, Galveston, Texas; University of Texas School of Medicine, Galveston, 1907; member of the State Medical Association of Texas; aged 57; died, August 6, of pulmonary edema and chronic nephritis.

James Anderson Gessing, Oak Park, Ill.; National Medical College, Chicago, 1897; member of the Illinois State Medical Society; aged 71; died, August 22, in the West Suburban Hospital of chronic myocarditis.

William Tone McMannis, New York; College of Physicians and Surgeons, medical department of Columbia College, New York, 1885; member of the Medical Society of the State of New York; aged 76; died, July 14.

Charles Leonard Randall, Salamanca, N. Y.; University of Buffalo School of Medicine, 1895; formerly county coroner and school physician; served during the World War; aged 73; died, July 27, of coronary thrombosis.

John Louis Hoffman ♂ Ashland, Pa.; University of Pennsylvania Medical Department, 1886; served during the World War; aged 76; died, August 11, in the Ashland State Hospital of myocarditis and arteriosclerosis.

Bernard DeKoven, Chicago; Columbia University College of Physicians and Surgeons, New York, 1904; aged 63; died, August 11, in the Michael Reese Hospital of myocarditis and chronic myelogenous leukemia.

Julius Wesley Hill, Richmond, Ky.; University of Louisville Medical Department, 1905; member of the Kentucky State Medical Association; aged 60; died, August 17, of arteriosclerosis and chronic nephritis.

Fanny Elizah Shutts, Los Angeles; Hahnemann Medical College of the Pacific, San Francisco, 1916; for many years member of the city health department; aged 65; died, July 5, in the Roosevelt Sanitarium.

Robert Ziegmond Garber, Ann Arbor, Mich.; University of Michigan Medical School, Ann Arbor, 1938; aged 26; died, August 6, in the University Hospital of pulmonary and intestinal tuberculosis.

Uriel Pierce Haw, Benton, Mo.; Vanderbilt University School of Medicine, Nashville, Tenn., 1898; member of the Missouri State Medical Association; aged 67; was shot and killed, July 23.

Isaac Newton Adams, Pineville, La.; Memphis (Tenn.) Hospital Medical College, 1901; member of the Louisiana State Medical Society; served during the World War; aged 63; died, July 25.

John Palmer Hollenback, New York; Creighton University School of Medicine, Omaha, 1937; resident surgeon on the staff of the Lenox Hill Hospital; aged 28; was found dead, July 21.

Bernard Reamy Le Roy, Stoutsville, Ohio; Western Reserve University Medical Department, Cleveland, 1885; veteran of the Spanish-American War; aged 80; died in July.

John A. Brady, Louisville, Ky.; University of Louisville (Ky.) Medical Department, 1893; served during the World War; aged 69; died, July 11, in the Kentucky Baptist Hospital.

Max Rosebery, New York; College of Physicians and Surgeons, medical department of Columbia College, New York, 1892; served during the World War; aged 71; died in July.

George Gordon Griffith, Spurgeon, Ind.; University of Louisville (Ky.) Medical Department, 1913; member of the Indiana State Medical Association; aged 50; died, July 3.

John Albert Reese, Detour, Mich.; University of Michigan Homeopathic Medical School, Ann Arbor, 1906; member of the Michigan State Medical Society; aged 60; died, July 15.

Joseph Clyde McCartney, Pelotas, Brazil; Medico-Chirurgical College of Philadelphia, 1886; also a dentist; aged 80; died, June 24, at sea while aboard the *S. S. Brazil*.

James Bray Bradley, Eaton Rapids, Mich.; Rush Medical College, Chicago, 1886; member of the Michigan State Medical Society; at one time mayor; aged 81; died, July 4.

William Wesley Hall, McLeansboro, Ill.; Rush Medical College, Chicago, 1883; member of the Illinois State Medical Society; aged 78; died, August 17, of carcinoma.

Thomas Richard Butler, Lexington, Mo.; Bellevue Hospital Medical College, New York, 1885; member of the Missouri State Medical Association; aged 77; died, July 4.

Llewelyn David Roberts, Hamilton, Mont.; Tulane University of Louisiana School of Medicine, New Orleans, 1938; aged 30; died, July 12, of chronic endocarditis.

Ernest Eugene Thompson, Red Bluff, Calif.; Cooper Medical College, San Francisco, 1900; member of the California Medical Association; aged 64; died, July 18.

John Camden Cochran, St. Marys, Pa.; Dartmouth Medical School, Hanover, N. H., 1890; Jefferson Medical College of Philadelphia, 1890; aged 84; died, July 18.

William E. Ford, Arlington, Va.; Maryland Medical College, Baltimore, 1909; served during the World War; aged 59; died, August 14, of diabetes mellitus.

Elmer C. Bond, Hanford, Calif.; California Medical College, San Francisco, 1899; member of the California Medical Association; aged 66; died, July 8.

Joseph David Michie ♂ Childress, Texas; Fort Worth School of Medicine, Medical Department of Fort Worth University, 1898; aged 67; died in July.

John Joseph Whoriskey ♂ Boston; Harvard Medical School, Boston, 1899; on the staff of St. Elizabeth's Hospital; aged 64; died, July 26, in Scituate.

Henry B. Gifford, Juda, Wis.; Rush Medical College, Chicago, 1883; aged 82; died, July 15, in Monroe of cerebral hemorrhage and chronic arthritis.

Ward Watson Wiers, Royal Oak, Mich.; Detroit College of Medicine, 1911; member of the Michigan State Medical Society; aged 64; died, July 13.

Louis William Rehbein, Los Angeles; Jefferson Medical College of Philadelphia, 1901; aged 68; died, July 13, of cerebral hemorrhage and arteriosclerosis.

Purvis Alexander Spain, Brooklyn; University and Bellevue Hospital Medical College, New York, 1899; aged 67; died, July 13, in the Wade Hospital.

B. Frank Eckman, Coral Gables, Fla.; Medical College of Ohio, Cincinnati, 1890; member of the Florida Medical Association; aged 72; died, July 9.

Israel Goldstein, Brooklyn; Columbia University College of Physicians and Surgeons, New York, 1922; aged 43; died, August 3, of angina pectoris.

George Walter Harding, Warsaw, Ind.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1886; aged 81; died, July 25.

Elbert Earl Freeman, Greentown, Ind.; Hering Medical College, Chicago, 1908; aged 59; died, August 11, of purpura haemorrhagica.

Edward Laughton Quirk, Aylmer (East), Que., Canada; McGill University Faculty of Medicine, Montreal, 1888; died about June 15.

William Patterson, Montreal, Que., Canada; University of Bishop College Faculty of Medicine, Montreal, 1884; aged 92; died, June 29.

William Frank Alvey, Louisville, Ky.; Chattanooga (Tenn.) Medical College, 1898; served during the World War; aged 67; died, July 29.

Oran Newton, Taft, Calif.; California Eclectic Medical College, Los Angeles, 1910; formerly health officer; aged 57; died, July 22.

Charles Augustus Ruffin ♂ Louisville, Ohio; University of Wooster Medical Department, Cleveland, 1906; aged 60; died, July 30.

William Franklin Markley, Follett, Texas; University of Kansas School of Medicine, Kansas City, Kan., 1906; aged 66; died, July 9.

Hilborn Wilton Harris ♂ Canton, Mo.; Missouri Medical College, St. Louis, 1888; aged 76; died, August 12, of coronary thrombosis.

George E. Kerns, Galion, Ohio; Eclectic Medical Institute, Cincinnati, 1903; aged 67; died, August 13, in Cleveland of pneumonia.

Arthur Philip Damerow ♂ Englewood, Colo.; University of Colorado School of Medicine, Denver, 1927; aged 40; died, June 5.

Joseph Aloysius Duffey ♂ Cincinnati; Eclectic Medical College, 1913; served during the World War; aged 49; died, July 9.

William F. Kellogg, Ethridge, Tenn.; University of the South Medical Department, Sewanee, 1898; aged 81; died, July 3.

Percy Leroy Jones, Lenexa, Kan.; Eclectic Medical Institute, Cincinnati, 1905; aged 62; died, June 26, of pneumonia.

James Addison Bell, Decatur, Ga.; Louisville (Ky.) Medical College, 1905; aged 59; died, July 7, of coronary disease.

Albert Jerome Britt, Philadelphia; Jefferson Medical College of Philadelphia, 1893; aged 68; died, July 26, in Rydal.

Mark Neumann, San Francisco; University of the City of New York Medical Department, 1880; aged 83; died, May 17.

Wilfred Joseph Heringer, Port Arthur, Ont., Canada; Manitoba Medical College, Winnipeg, 1913; died, June 30.

Robert a'Beckett Stephenson, Inglewood, Calif.; Rush Medical College, Chicago, 1903; aged 65; died, May 17.

James A. Delaney, Bristol, Tenn.; Hospital College of Medicine, Louisville, Ky., 1895; aged 70; died, July 23.

George Lyman Woods, Knoxville, Tenn.; Medical School of Maine, Portland, 1879; aged 90; died, July 28.

Alonzo Bittle Curtis, Lower Peach Tree, Ala.; Medical College of Alabama, Mobile, 1882; died, July 23.

Oliver I. Hess, Scottsdale, Pa.; Kentucky School of Medicine, Louisville, 1894; aged 86; died, July 9.

J. M. Parks, Elkhart, Texas (licensed in Texas, under the act of 1907); aged 84; died, July 16.

John C. Luke, Ocilla, Ga.; Louisville (Ky.) Medical College, 1893; aged 70; died, July 1.

R. Pierce White, Stovall, Ga.; Atlanta Medical College, 1884; aged 80; died, July 18.

Bureau of Investigation

DARK AGES STILL WITH US
Seven U. S. Post Office Fraud Orders Against
"Cure-Alls"

There can be no such remedy as a "cure-all." By this time every one ought to know that not even sulfanilamide is a panacea. Nevertheless, some concerns still find it profitable to advocate a remedy or a line of remedies for the treatment of practically everything. There is evidence to indicate that one

files of the Bureau of Investigation. At this late date however it is hoped that, since these remedies have their appeal only to the unintelligent, these promotions are not of sufficient importance to warrant separate articles in the pages of a scientific publication.

The group of seven were subjects of fraud orders issued during the past year and serve to illustrate the extent to which such promoters carry on their activities and also to illustrate the laudable action of the Post Office Department in these cases. Table 1 gives the name and location of each firm and the names of the remedies which were promoted, while table 2 indicates the conditions in which these remedies were advo-

TABLE 1.—*Fraud Orders Referred to in This Article*

Names of Individuals and Companies	Location	Remedies Named	Date of Issue	Order Number
Arrowhead Indian Herbs Company... Dewey Conway, Jodie Conway	Chico, Calif.	Remedy No. 19-D; No. 28-D; No. 138-D; No. 240-D; No. 297-D; No. 6-D; No. 7-D; No. 14-D; No. 104-D; No. 29-L	July 20, 1940	14417
Botanical Medicine Company..... Dr. W. B. Goebel	Kannapolis, N. C.	Gall Bladder Special; Pyorrhea Treatment; Trifolium; Lav-I-Ton; Ironite; Black Spirit; Femdyne; Ey-No-La; Hem-I-Rin; Kre-Cal	Jan. 22, 1940	13700

Theodore M. Moore..... Prof. Theodore M. Moore	Davenport, Iowa	Big 4 Wonders Indian Remedies; Spirit Luke Salts; Big 4 Wonders Iron Tonic; Black Bath Mineral; X X White, Mineral; Stomach Capsules; Vaginal Suppositories; Mineral Laxatives	Dec. 4, 1939	13576

TABLE 2.—*Résumé of Fraudulent "Cure-Alls," Referred to in This Article*

Name of the Promoter of the Remedies	Diseases for Which the Remedies Were to Be Used																Other Conditions Specifically Mentioned in the Advertisements	
	Apparently Any Al- liment or Disorder	Asthma	Anemia	Bladder Diseases	Cancer	Diabetes	Eye Diseases	Female Disorders	Hemorrhoids	High Blood Pressure	Kidney Diseases	Malaria	Piles	Pyorrhea	Rheumatism	Sores		Stomach Troubles
Arrowhead Indian Herbs.....	X																	Gallbladder troubles, gallstones
Botanical Medicine Co.....	x	x	..	x	x	x	x	x	x	..	x	x	x	x	x	Diphtheria, dropsy, lung trouble, loss of manhood, menopause
Crocker's Asthma and Lung Trouble Medicine Co.	..	x	x	x	x	Abscesses, adenoids, bronchitis, diarrhea, earache, leukorrhea, delayed and painful menstruation, nasal catarrh, nervousness, neu- ritis, ovary troubles, tonsils, fall- ing womb
H. W. Lange & Son.....	x	x	x	x	Loss of hearing, gallstones, gas- tritis, skin diseases, running sores, all tumors
Morehead & Co.....	X	x	x	x	..	x	..	x	x	x	x	x	x	..	x	..	x	Blood purifier, constipation, eczema, "social" diseases
Prof. C. A. Isbell.....	x	x	x	x	x	x	x	Deafness, failing eyesight, paral- ysis, sleeping sickness, tuberculosis, insanity, syphilis
Theodore M. Moore.....	X	x	..	x	x	x	..	x	x	x	x	x	x	..	x	

promoter who at various times seems to have interested himself in some of the above-named products, was apparently not satisfied with the extent of this fraud and included in his advertising some of the old Albert Abrams hokum: "A Complete Blood Test—Radio-Electronic Diagnosis and Treatments." "One Drop of Your Blood" said he, would reveal whether you had "cancer, tuberculosis, blood infections or other ailments" and whether these conditions would be "curable or incurable" in your case.

Much more in the way of history of some of the concerns named in the tables could be developed in this article from the

cated. Of special note are those which were apparently promoted for any ailment or disorder as well as those which were suggested as remedies for diabetes, diphtheria, tuberculosis, sleeping sickness, insanity and syphilis.

The Post Office Department is to be commended for refusing the use of the United States mails to these concerns. It is to be hoped that all other such remedies will be subjects of similar fraud orders issued at an early date. It is also to be hoped that whatever portion of the American public comprises the purchasers of these remedies will soon be educated to the point where the sale of such items reaches absolute zero.

Correspondence

SERUM CENTER IN IOWA

To the Editor:—My attention has been called to an item in THE JOURNAL of August 10 under Queries and Minor Notes, page 480, on convalescent serum for contagious diseases. In referring to sources of convalescent serum the State of Iowa Department of Health is not mentioned.

I therefore wish to add that in 1937 the State of Iowa Department of Health organized its serum center for the processing of human immune serum. Since its organization the Serum Center has distributed a total of 213,000 cc. of human serum. Of this amount 23,655 cc. has been distributed for measles, 135,490 cc. for scarlet fever and 42,980 cc. for poliomyelitis. Lesser amounts have been processed for Rocky Mountain spotted fever, pertussis and tularemia. The convalescent serum is sent to licensed physicians on request without charge. When the economic status of the patient permits, a contribution is accepted to the donor's fund. Donors are paid \$5 for 250 cc. of blood. The attending physician is expected to send a complete clinical report of all cases in which the convalescent serum is used. The serum center is at present also processing human serum for transfusion purposes in accordance with the procedure of Carlson and Levinson. The State of Iowa Department of Health is the one state department at the present time processing convalescent serum.

The Serum Center was properly licensed by the Federal Security Agency, National Health Institute, Division of Biologics Control in September 1939. At that time the license granted interstate traffic to measles, scarlet fever and poliomyelitis human immune serum and normal human serum. Later, in May 1940, the license was extended to include pertussis immune serum.

WALTER L. BIERRING, M.D., Des Moines, Iowa.

Commissioner, State of Iowa Department of Health.

HEALTH SERVICE SYSTEM OF SAN FRANCISCO

To the Editor:—In THE JOURNAL (August 17, p. 540) under the heading Organization Section, you carry an article on the health service system of San Francisco.

Your readers should know that the statements and statistics in this article are taken from a pamphlet prepared by the lay board that operates the system. The physicians who actually perform the services under the system (over 95 per cent of whom are members of the San Francisco County Medical Society) presented an analysis of the report in the May 1940 issue of the *Bulletin of the San Francisco County Medical Society*.

It is important for your readers to note that the chief complaint of the physicians has not been that the value of the unit was too low. It has been that the system has been conducted in an arbitrary manner, with very slight attempts on the part of the director to cooperate with the county medical society. The official manager's report conceals the fact that in 1939 the physicians actually contributed more than \$132,000 worth of medical services without remuneration, this sum being based on the modest schedule in effect during that year. It is readily admitted that the employees called for an unreasonably large amount of medical service. Nevertheless, if the visits and services actually made (but arbitrarily disallowed) were included in the computation of the unit paid, it would reveal the fact that the doctors were paid about 50 cents on the dollar.

The physicians of San Francisco are happy to cooperate with any constructive voluntary health insurance system in the operation of which they have a proper voice. They do believe, however, that the true facts should be known, since faulty conclusions could easily be drawn from the figures you publish.

L. HENRY GARLAND, M.D., San Francisco.

Secretary, San Francisco County Medical Society.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

"METAL FUME FEVER" IN WELDERS

To the Editor:—My attention has been called to a condition of vertigo, profuse perspiration, dyspnea and rapid pulse suffered by men using the electric welding apparatus on galvanized material at the Pearl Harbor Navy Yard. Recently several patients have consulted me primarily for a nasal congestion and a wet nose together with some vertigo and ocular instability. They all gave the history of having worked either as an electric welder or in close connection with this kind of work. I am wondering if there is a possibility that these patients are suffering from a poisonous effect from the gas generated by such a job. Have you anything in your files concerning this type of poisonous gas and if so would you please send me a digest of it or tell me where it can be found?

M.D., Honolulu, T. H.

ANSWER.—A considerable number of cases of metal fume fever have been reported in past years among welders engaged in the welding or cutting of galvanized steel in naval vessels, particularly in confined spaces. The condition now is comparatively infrequent owing to the efficiency of the protective measures which have been introduced.

The galvanized coating is basically zinc and contains from 95 to 96.5 per cent of that metal. It also contains from 0.75 to 1 per cent of lead and from 2.5 to 4 per cent of iron. Metal fume fever results from the inhalation of zinc oxide fumes incident to the welding or the cutting of the metal, lead being present in such traces as to be apparently negligible.

Metal fume fever has long been recognized as an industrial disease. Other terms commonly applied to the condition are brass foundry's ague, brass chills and zinc fever. At one time it was of common occurrence among brass foundry and zinc smelting workers. Generally attacks today are found as a result of welding or cutting of galvanized sheets and pipes.

It is an acute, transitory, nonfatal disease causing slight or temporary disability. A strict interpretation of the term metal fume fever does not place it in the class of conditions termed metal poisoning. The reaction set up in the body is not directly ascribed to the toxic metal or dependent on the inherent toxicity of the metal particles inhaled. The superficial action of the inhaled finely divided zinc oxide injures the epithelial cells lining the respiratory tract. The absorption of the altered proteins of these cells affects the individual much the same as the typhoid inoculation or the injection of other foreign protein.

At the end of the day, or from two to twelve hours following exposure to the zinc fumes, the worker notices a dryness of the throat in addition to a metallic taste which most workers commonly report during exposure. There is usually a feeling of tightness of the chest, varying with the exposure. This tends to indicate the severity of chills and fever which are to follow. Occasionally nausea and vomiting occur. When mildly affected the patient may not be aware of any fever and complain only of a chilly sensation followed by sweating and general weakness. Exposure to extreme cold may hasten the onset of the fever and chills, but as a rule the worker awakens from sleep with a high temperature and chills, which are quite similar to the chills and fever experienced in attacks of malaria. Toward the end of the attack the individual sweats profusely and is left with a feeling of weakness. In the majority of cases some weakness is still felt the next day. The time loss, however, is rarely beyond one day.

Metal fume fever may sometimes be overlooked unless the physician considers the occupational environment. It may simulate attacks of grip or bronchitis or, if in a malarial region, it may be mistaken for an attack of malaria. Continued work

produces an immunity or raises resistance, but this is lost after a layoff from work.

There appears to be no conclusive evidence that chronic effects are produced by repeated exposure to zinc fumes.

The prevention of metal fume fever in welding is accomplished in naval vessels by means of localized exhaust, the fumes being removed at the source. A light metal pipe approximately $3\frac{1}{2}$ inches in diameter connected to an exhaust blower serves to remove the bulk of the zinc fumes at the line of the weld. This is carried along with the work from place to place. In addition, respirators are provided for special protection under unusual circumstances. Ordinarily the localized exhaust, if used in compliance with instructions, is adequate to prevent metal fume poisoning.

ULTRAVIOLET RAYS FOR AIR STERILIZATION IN AIR CONDITIONING SYSTEMS

To the Editor:—There has been considerable discussion concerning the use of ultraviolet rays in air conditioning systems for sterilizing the air, particularly because in many systems in which the air is cooled approximately 75 per cent is recirculated from the cooled space, with the possibility that it might carry bacteria. Ultraviolet rays, if used, would be introduced into the recirculated air path, where the velocity may be as high as 1,000 feet per minute. There is a question as to whether such an arrangement would be effective and also a question as to the results that might be accomplished with ultraviolet rays even though the velocity of the air passing the ultraviolet source is not so great. Any information you can supply concerning this matter would be appreciated.

M.D., Wisconsin.

ANSWER.—Wells, investigator of air-borne bacteria and ultraviolet rays for bactericidal purposes, in a recent publication (*J. Franklin Inst.* 229:347 [March] 1940) provides much information dealing with the points raised in this query. In a smooth tunnel 100 feet long, the other dimensions being 7 by 8 feet, a standard ultraviolet lamp was set up near the center. At the air entry end of the tunnel, *Escherichia coli* cultures were sprayed into the atmosphere. Various determinations were made as to the killing action of ultraviolet emanations under various conditions, including velocity, humidity and nearness to the lamp. At a velocity of 222 feet per minute and a relative humidity of 43 per cent, when the bacterial count prior to ultraviolet action was 1,250 per sample, a drop to 303 bacteria occurred after passing the rays. At a velocity of 21 feet and a relative humidity of 67 per cent, the count before exposure of 42,000 bacteria dropped to 12,500 after action of the rays.

In another publication (*Am. J. Pub. Health* 29:863 [Aug.] 1939) Wells and his associates report some bacterial counts made in an air conditioned railway car with and without the action of ultraviolet rays in the air conditioning. On this car the passenger load varied from one to sixty-nine. With the ultraviolet rays turned off and a passenger load of one, the total bacteria count was 232. When the passenger load was sixty-nine the bacterial count was 1,324. When the ultraviolet rays were operating, at a time when the passenger load was fifteen, the lowest reported in this particular series of experiments, the bacteria count was 349, the highest count in this series of samples. When, however, the passenger load was fifty-five the bacterial count was in one sample 186, the lowest figure associated with any passenger load.

From all experimental work, several complex formulas have been devised permitting computations under varying circumstances as to intensity of radiation, air velocity, type of air flow, distance from the rays and the like. The mere introduction of ultraviolet units in the conduits of an air conditioning system affords no assurance of extensive bactericidal action. Conversely, full consideration for all factors involved might indicate sets of ultraviolet radiating facilities sufficient to cope with any air velocity and bacterial load. The practicability of such equipment under some circumstances is open to debate. Nothing in the publications of Wells as cited suggests that with an assumed

velocity of 1,000 linear feet per minute a near-sterile air may be obtained. On the other hand, it is to be recognized that suitable intensities and suitable distribution of ultraviolet lamps in connection with air conditioning will effect some reduction in atmospheric bacterial contamination.

DERMATALGIA

To the Editor:—A woman aged 83, usually in good health, three months ago developed intertrigo between her thighs. This healed with slight medication. Six weeks later her feet at night became uncomfortable because of warmth heat. I do not find this discussed in available textbooks. Nothing I have prescribed has been of benefit. She is compelled to sleep with her feet exposed. She is kept awake from two to four hours each night. Her discomfort is distressing. The patient is a college graduate and is not neurotic or unusually sensitive. I have tried many lotions and the like and have consulted with my medical friends. I do not find the condition discussed in medical books available.

M.D., New Jersey.

ANSWER.—From the description it is assumed that there is no change in the appearance of the skin during attacks, thus justifying the diagnosis of dermatalgia, a disturbance of the nerves supplying the skin of the part affected, supposedly the nerves of the vegetative system. The pain varies in different cases, burning as in the case cited, or a sensation of hot or cold water running over the skin, of stabbing, cutting, rubbing of the skin, or the sensation of an electric current. The attacks come on usually at night, affect middle aged women most often and are commonly associated with hyperesthesia so that the contact of clothing or other objects adds to the distress. Hair parts or the extremities are most often involved.

This disease was discussed in answer to a query on page 739 of THE JOURNAL, Aug. 31, 1935. As possible etiologic factors tabes dorsalis, malaria, rheumatism, diabetes mellitus, leukemia and other members of the lymphoblastoma group and leprosy were mentioned. In addition chlorosis, hysteria and any cause of neuritis are mentioned in the literature. Exposure to cold is also mentioned, probably the reason for the mention of rheumatism. It might be well to examine for anemia and the possibility of certain forms of avitaminosis, especially those in which elements of the vitamin B complex are concerned.

If any such cause can be discovered, treatment directed accordingly may succeed in eradicating the pain. If not and in the considerable proportion of the cases in which no such basis can be found, acetylsalicylic acid, salicin, quinine and arsenic are recommended and the local use of alternating hot and cold applications, galvanic or faradic electricity, or counterirritation over the nerves supplying the part. Langeron and Desplats are quoted as having suggested roentgen therapy over the sympathetic centers for the relief of the pain of dermatalgia. The reference given in the article on dermalgie in the *Nouvelle pratique dermatologique*, volume 5, page 759, is incorrect and the article of Langeron and Desplats has not been traced. A small dose of roentgen rays, from 40 to 80 roentgens filtered through 2 mm. of aluminum, may be effective. This can be repeated at weekly intervals.

As advised in the query of 1935, the skin should be protected as well as possible from the irritation of clothing.

LEAD IN INSULATING MATERIAL

To the Editor:—Have you any information concerning the possibility of lead poisoning to the occupants of a house which is insulated by a material made by the Eagle Picher Company. This material is made from lead slag as a base and is a by-product of the refinement of lead ore. There might be slight sifting through plaster cracks and if the material is not entirely inert there might be an appreciable danger.

George B. Stericker, M.D., Springfield, Ill.

ANSWER.—The chemical composition of Eagle Mineral Wool Home Insulation has been supplied by the firm as follows:

Iron silicate	54.82%
Aluminum silicate	7.40
Calcium silicate	24.23
Magnesium silicate	3.39
Lead silicate61
Manganese silicate57
Zinc oxide	9.46
	100.48%

While the constituents listed total more than 100 per cent, the excess may be charged to experimental error. It should be noted that most of the constituents in this mineral wool are in the form of silicates and the trace of lead silicate present is highly insoluble and is regularly used as a constituent of high grade tableware. The possibility of lead poisoning from this

source is rather remote because of the small proportion of lead in the material and the small amount of insulation which might seep through cracks in the plaster. Although this situation does illustrate another potential lead exposure of the general population, the insulation in question with its present chemical constituents has been manufactured and sold in large quantities for more than ten years without knowledge on the part of the manufacturers of a single case (including those handling the installation contracts) of any form of illness or disease resulting from the material.

CHRONIC SAPHENOUS PHLEBITIS AND POSSIBLE EMBOLISM

To the Editor:—On March 7, 1940, a married woman aged 46 developed a sudden pain in the right chest. I examined her chest and found no gross abnormality and made a diagnosis of acute pleurisy. Four hours later I reexamined the patient and discovered an area of consolidation involving the right middle lobe. A variety of râles were present. She coughed and expectorated some bloody sputum. The pulse rate was 130 and the temperature was 100 F. I made a provisional diagnosis of pneumonia. At the hospital the white count was 14,000. A few of the higher type pneumococci were found in the sputum. X-ray examination revealed irregular consolidation of the entire right lung suggesting pneumonia. This cleared in about ten days both clinically and roentgenologically with no specific medication. The temperature ranged between 100 and 101 F. for a week. Nine months previously she had cardiac arrhythmia and she complained about dyspnea. This led a colleague and me to think about the possibility of a pulmonary embolus. She was given only digitalis and morphine. About one week after the onset of the illness phlebitis of the first saphenous vein above the thigh was noted. It was then thought that an embolus developed from this site, although the patient did not complain until later. One consultant felt that the phlebitis was secondary to a pneumonia. On March 20 the patient was discharged apparently well. The pulse rate was 90. There was no fever, and pain in the leg was slight. On March 27, after an attack of coryza, there was a recurrence of the phlebitis. The temperature varied between 99 and 100 F. The average is 99.6 F., in the afternoon and has continued so for nearly four months. The first saphenous vein is painful and tender and feels beaded on palpation. The pulse rate remains at 90. The chest appears clear and there are no chest symptoms. The leg is not swollen and has never been swollen. The patient has been in bed since the onset of her illness. A patch tuberculin test was negative. This was done because of a positive history of tuberculosis in the family. Sputum tests were negative for acid fast organisms. Urinalysis and blood chemistry were normal. The blood Wassermann reaction was negative. X-ray examination of the chest was not repeated because I have feared to have her get out of bed because of the possibility of embolism. My patient has become quite discouraged because there has been no improvement with prolonged rest. I told her that she would be permitted to get up after the temperature remained normal for a time. I hesitate to allow her out of bed because of the possibility of embolism and the possibility of aggravating the inflammation. Treatment has been conservative. Moist and dry heat have been applied locally to the veins. Is this an unusual duration of fever with phlebitis? How long can I expect this fever to continue? What can be done to shorten the course of the inflammation? Would I be justified in using foreign protein therapy?

Joseph F. Lechman, M.D., Latrobe, Pa.

ANSWER:—The description of the initial attack may well fit the picture of pulmonary embolism but the origin of the embolus is obscure. One would have to know whether a pelvic phlebitis is present, which often accompanies infections of the female genitals. A previous history of pain and swelling following childbirth or operation might give a hint as to the existence of a latent pelvic thrombosis. The existence of varicosities is not mentioned in the query. The fact that a saphenous phlebitis followed instead of having preceded the suspected infarct is not unusual, as short clots in the external or internal iliac veins often show a retrograde extension into the veins of the lower extremities after the appearance of the infarct.

Phlebitis following pneumonia is, of course, an equally good possibility; however, it usually appears in a form of an ilio-femoral phlebitis causing swelling, discoloration and visible distention of the superficial veins.

The following methods of treatment are worthy of consideration: (1) eradication of all foci of infection, especially in the teeth and tonsils, (2) small doses of roentgen rays (100 roentgens with heavy filter) at weekly intervals, (3) small doses (from 2 to 2.6 Gm.) of sulfanilamide for from ten days to two weeks. The virulence of the process can be gaged best by the sedimentation rate. If this is a true saphenous phlebitis without involvement of the deep veins there is no need to keep the patient immobilized; the saphenous vein can be tied at its junction with the femoral, thus excluding a possible source of emboli. The division of the vein often hastens the subsidence of phlebitis. If the coagulation time is too short, heparin or leeches are often helpful. The decision as to when to let the patient get up and which of the methods mentioned should be employed requires considerable clinical experience. Recurrent phlebitis and embolism may occur as late as eight years after the initial attack.

A PATENTED ORAL TREATMENT FOR HAY FEVER

To the Editor:—I have heard something about a pollen mixture in yeast of bread making for treatment of hay fever. It was stated that such a patent was given to a Kurt Rosenwald of New York. Could you give me any information on this method?

Leslie S. Harrison, M.D., Bayside, N. Y.

ANSWER:—U. S. Patent 2,207,415, issued July 9, 1940, to Kurt Rosenwald of New York, is described as "the peroral treatment of hay fever in a therapeutical preparation, in which the principal effecting ingredient is a decomposition product of the protein of the pollen of at least one hay-fever-causing plant to which the patient is sensitive, said decomposition product being formed by the action of yeast on said pollen." Apparently this claim of therapy in hay fever is based on the supposition that a digestion product of the pollen taken by mouth will produce some form of immunization. The inventor adds yeast and pollen to a food or drink, such as bread dough, grape juice or beer. In some respects this treatment resembles that proposed a number of years ago by Urbach, in which propeptones of pollen were administered. Since oral pollen therapy has been found to have little if any effectiveness, since Urbach's propeptones have been virtually discarded, at least in this country, and since the proteolytic action of yeast cannot be expected to be more effective than the proteolytic action of the gastrointestinal enzymes, it is difficult to understand how such therapy can be expected to operate.

FATTY DEGENERATION AND INFILTRATION OF HEART

To the Editor:—In Modern Concepts of Cardiovascular Disease (published by the American Heart Association), in volume 7, No. 9 (Sept.) 1938, appears the following statement: "When excess deposits of fat occur in the subpericardial space, penetration or infiltration of fat into the connective tissues lying between the muscle bundles occurs, and at times the penetration occurs between the individual muscle fibers but not into the muscle cell." In an article by E. Perry McCullagh of Cleveland (Management of Obesity, *Ohio State M. J.* 3-4: 1131 [Oct.] 1938), under Clinical Manifestations, the following statement appears: "The heart may be embarrassed for several reasons. It is encroached upon by fat either about the heart, between the muscle fibers, or in the cells themselves." Which view is correct?

Richard P. Shapiro, M.D., Philadelphia.

ANSWER:—Fatty infiltration between the heart muscle bundles is a common observation, especially in the obese, as in middle aged and elderly women, particularly involving the right ventricle; but fat in the muscle cells themselves occurs only in strictly disease conditions in which there is degeneration of the cells, as in the first stages of infarction or other serious involvement of the myocardium per se. Of course it is possible to have both fatty infiltration and fatty degeneration in the same patient, but either may occur alone.

SENSITIVITY TO LIVER PREPARATIONS

To the Editor:—A woman aged 38 suffering from primary anemia has been under treatment for ten years, recently taking an oral preparation which has maintained her blood picture essentially normal, other than for minor poikilocytosis, and has kept her entirely free from symptoms. The cost of this preparation, however, is considerable—about \$15 every six weeks—and this works a definite hardship on her. She has tried raw liver and numerous other preparations containing liver, but nausea prevents therapy other than in capsule form orally. There is a history of the use of parenteral liver therapy about eight years ago, but reactions were so severe that she had to give up this form of therapy. I have recently started treatment with a concentrated liver solution containing 10 U. S. P. units per cubic centimeter. Three injections at weekly intervals caused no untoward response, but the fourth brought forth a typical allergic phenomenon with urticaria and circumscribed and circumbulbar flushing and edema. This reaction lasted about twenty-four hours and then subsided. The next parenteral injection is due next week, and I intend changing to a more refined preparation of 15 U. S. P. units per cubic centimeter. If the reaction still occurs, which is the better course of procedure—to change back to oral liver, which I am reluctant to do, to administer liver therapy with ephedrine sulfate and a barbituric acid derivative parenterally or to try desensitization. If the latter, how may it be carried out and, if once desensitized, will sensitivity redevelop in the intervals between weekly injections?

M.D., Massachusetts.

ANSWER:—Allergy to liver extract in a patient with pernicious anemia is a distressing and sometimes serious situation. Parenteral extract of several different manufacturers might be tried first. It is usually possible to find a preparation to which the patient is not sensitive. It is well to use the most concentrated extracts available, with the hope that the antigenic substance has been eliminated by refining. Trying to give a liver extract to which the patient is known to be sensitive and then attempting to control the reaction with drugs is not advised. Desensitization is not often successful. If a preparation cannot be found to which the patient is not allergic, oral therapy should be continued.

MORPHINE AND PARALDEHYDE

To the Editor:—Have you any information on synergistic toxicity in the use of paraldehyde and morphine? A recent article in a trade publication mentioned that the use of these drugs together may produce serious results.
M.D., Virginia.

ANSWER:—A search of the literature has failed to show any work which would confirm the statement that paraldehyde and morphine when used simultaneously have a synergistic toxicity. One of the widely used methods of controlling eclampsia consists in the intravenous administration of paraldehyde and at the same time the hypodermic use of from one-fourth to one-half grain (0.016 to 0.032 Gm.) of morphine sulfate.

Paraldehyde in therapeutic doses does not depress the heart or respiration. In many cases it seems to exert a stimulating action.

POSSIBLE SENSITIZATION TO DIGITALIS

To the Editor:—Can the human body occasionally become sensitized to digitalis? In August 1939 I gave an excess of digitalis to a 64 year old woman with the usual after-symptoms of overdosage. Later, with the advice of a good cardiologist, I gave one-third tablet of gitalin daily for months. In April of this year I gave her 9 grains (0.6 Gm.) of standard digitalis within twenty-four hours, thinking I saw indications. She had an extreme gastric upset which lasted to some degree for ten days. I then stopped all medication and continued bed rest for thirty days and started the gitalin, one-third tablet daily. The second third of a tablet was followed by gastric pain occurring six or eight hours after and lasting two or three hours with definite fall of pulse rate (from 85 to 55 and 60) and gastric upset. I am inclined to feel that she was suffering from the two small doses and is therefore sensitized to digitalis and its preparations.
J. D. Michie, M.D., Childress, Texas.

ANSWER:—While it is unwise to say that certain things never happen in the field of medicine, especially in allergy, a careful perusal of the literature shows no reference to allergic intolerance of digitalis. The following works, limited to digitalis, fail to mention this as a possibility: Heftner, A.: *Handbuch der experimentellen Pharmakologie*, Berlin, Julius Springer, 1935, vol. 1; Weese, H.: *Digitalis*, Leipzig, Georg Thieme, 1936. Nor does a general manual of pharmacology, like that by Solfmann (fifth edition, 1936), mention this as a possibility. It seems probable from the history given that the reaction described is not allergic.

PROSTIGMINE COMPOUNDS AND GLAUCOMA

To the Editor:—A patient is being treated for moderate glaucoma with drops of pilocarpine solution. She has some ear trouble (blocking of eustachian tubes) and the otologist prescribed prostigmine bromide 15 mg. three times a day and prostigmine methylsulfate (1:2,000) by injection twice weekly. Will this treatment be detrimental or have any effect on the eye? The otologist does not want to give an opinion. Will this treatment have any effect on the eye muscles as in myasthenia gravis?
B. O. LeBlanc, M.D., St. Gabriel, La.

ANSWER:—The preparations of prostigmine mentioned would not have any detrimental effect on the eye. It is even possible that they might have a beneficial effect in the case of glaucoma, although this is certainly doubtful. Prostigmine compounds are, of course, closely related to those of physostigmine and are used in the form of drops as a substitute in some cases of glaucoma.

DISCHARGING BREAST

To the Editor:—A woman aged 46 has one breast that has been discharging a thin yellowish to a fairly thick yellowish serous fluid for the past ten or eleven years, since her last child was born. One year ago this breast discharged a light bloody fluid for about two weeks, then a dark bloody fluid for two weeks and thereafter the serous fluid again. Recently the bloody discharge has begun again. There are no masses, no induration, no shadows on transillumination, no pain and no tenderness. Estrogen has been given without any noticeable result. I am especially interested to know whether there would be any value in administering 1:4,000 prostigmine methylsulfate solution in an attempt to clear up the discharge from a breast which gives absolutely no shadow of any kind on careful transillumination.
M.D., Texas.

ANSWER:—In view of the long-standing history and the completely negative physical examination, one is inclined to assume that at present a malignant condition is not apparent, although it might be microscopic. It is difficult to understand how prostigmine methylsulfate solution could inhibit the discharge. Possibly testosterone propionate might be of benefit, at least temporarily, by causing involution of the breasts. Twenty-five mg. of testosterone propionate, in such instances, is injected subcutaneously three times a week for a period of from four to six weeks. The danger of producing virilism, such as hirsutism, change in voice and enlargement of the clitoris, cannot be overlooked. However, the suggested dose is not large and the risk is probably slight. Furthermore, signs of virilism practically

always disappear when the drug is discontinued. The discharge may stop spontaneously when the ovaries cease to function. If testosterone propionate does not inhibit the discharge, radiation therapy to the ovaries may be considered. There is not likely to be harm in this procedure because the patient is 46 years old.

ONYCHOGRYPHOSIS

To the Editor:—A man aged 44 has onychogryphosis. He is a produce merchant in a vegetable market. The nails affected are those of the two index fingers and the condition seems to be directly attributable to the constant lifting of cases of iceberg lettuce by the use of both index fingers. It has had a gradual onset for six weeks. For three weeks I pared the thickened nails down to the matrix, applied a 3 per cent salicylic acid ointment, used warm soaks, and now am trying to restore the nutrition of the nail and fingers with diathermy. The literature gives a paucity of information concerning its cure. I have been unable to cure his condition. Could you please give me the latest opinions as to etiology and effective therapy in onychogryphosis.

Vincent J. Barone, M.D., Elmhurst, Queens, N. Y.

ANSWER:—In onychogryphosis the nail becomes enormously thickened and clawlike. Pressure, warmth and lack of proper care are contributing causes. Thickened and enlarged nails are at times observed in leprosy, tuberculosis, acromegaly and syringomyelia. The hypertrophic changes may often be found in association with local irritation or injury and with gout, rheumatism and certain diseases, e. g. eczema, paronychia, psoriasis and occupational dermatitis.

It is suggested that trauma be avoided as far as possible; the patient might consider wearing canvas gloves at his work, and careful cleanliness and regular manicure of nails should be insisted on.

An unusual case of onychogryphosis on the basis of a combination of rheumatism and lack of care in a patient aged 73 was reported by Wien and Perlstein (*Arch. Dermat. & Syph.* 28:807 [Dec.] 1933).

POSSIBLE HOMOSEXUAL TENDENCIES

To the Editor:—A man whose standing, personally and professionally, has always been beyond reproach or question has been accused of improper sex relations with other men, these men stating that he approached them not by question but by touch. It has been established that the men in question are of somewhat doubtful character and one of them, at least, has reason to wish this man harm. The man's personal life is far above the average; he has a wife and children and is splendidly educated. I cannot find it possible to believe such accusations. He has denied them and was shocked beyond belief at having them made. He is perfectly willing to undergo any examination, physical or psychologic, which would assist in proving him innocent or incapable of such conduct. The problem presented is: What examinations? I have never before been confronted with such a matter, have no literature dealing with it and am at a total loss as to procedure. This matter is vitally important to this man's career.
M.D., Florida.

ANSWER:—The patient should be given a complete medical and psychiatric examination. Any standard textbook of psychiatry outlines the routine psychiatric form to be followed. The following textbooks are suggested:

Henderson, D. K., and Gillespie, R. D.: *A Textbook of Psychiatry*, ed. 4, New York, Oxford University Press, 1938.
Singer, H. D., and Krohn, W. O.: *Insanity and Law*, Philadelphia, P. Blakiston's Sons & Co., 1924.

The problem in this case may be one of homosexual tendencies in an otherwise normal person. It is well known that such homosexual tendencies are merely arrests in psychologic development and that such people may marry and have a perfectly happy family life but may continue to exhibit homosexual interests. They require prolonged psychotherapeutic help and should be under the direct care of a psychiatrist. Many of them can be helped, but, more important, they must be protected from hostile and often trouble-making persons in their environment.

CHRONIC NODULAR PHLEBITIS

To the Editor:—A patient has a series of small nodules within the walls of the brachial vein and its branches in the forearm. They are accompanied by numbness in the forearm. The patient is a man aged 32 and has always been well. The Wassermann reaction is negative. What might these small hard nodules be?
C. W. Henney, M.D., Portage, Wis.

ANSWER:—The syndrome of chronic nodular phlebitis has been described by Gougerot. It may be due to low grade pyogenic, tuberculous, syphilitic or mycotic infection. The nodules may form sharp edged, poorly granulating ulcers with a yellowish base. There is no fever or glandular involvement. When seen early the granuloma is under the intima and may resemble a rheumatic nodule. In this particular case, because of the associated numbness, one should think of the possibility of a neurofibromatosis of Recklinghausen originating from the sheaths of peripheral nerves.

Medical Examinations and Licensure

COMING EXAMINATIONS

NATIONAL BOARD OF MEDICAL EXAMINERS EXAMINING BOARDS IN SPECIALTIES

Examinations of the National Board of Medical Examiners and Examining Boards in Specialties were published in THE JOURNAL, September 21, page 1043.

BOARDS OF MEDICAL EXAMINERS

ALABAMA: Montgomery, June 17-19. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

ARIZONA: * *Written*. Phoenix, Oct. 1. *Reciprocity*. Phoenix, Oct. 2. Sec., Dr. J. H. Patterson, 326 Security Bldg., Phoenix.

ARKANSAS: * *Regular*. Little Rock, Nov. 7-8. Sec., Dr. D. L. Owens, Harrison, *Eclectic*. Little Rock, Nov. 7. Sec., Dr. Clarence H. Young, 1415 Main St., Little Rock.

CALIFORNIA: *Oral examination* (required when reciprocity application is based on a state certificate or license issued ten or more years before filing application in California), San Francisco, Oct. 2. *Written examination*. Sacramento, Oct. 21-24. Sec., Dr. Charles B. Pinkham, 1020 N St., Sacramento.

CONNECTICUT: * *Written*. Hartford, Nov. 12-13. *Endorsement*. Hartford, Nov. 26. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden. *Homoeopathic*. Derby, Nov. 12-13. Sec., Dr. Joseph H. Evans, 1488 Chapel St., New Haven.

DELAWARE: July 8-10. Sec., Medical Council of Delaware, Dr. Joseph S. McDaniels, 229 S. State St., Dover.

DISTRICT OF COLUMBIA: * *Washington*, Nov. 11-12. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

FLORIDA: * *Tampa*, Nov. 18-19. Sec., Dr. W. M. Rowlett, Box 786, Tampa.

GEORGIA: Atlanta, Oct. 8-9. Joint-Sec., State Examining Boards, Mr. R. C. Coleman, 111 State Capitol, Atlanta.

HAWAII: Honolulu, Jan. 8-11. Sec., Dr. James A. Morgan, 48 Young Building, Honolulu.

IDAHO: Boise, Oct. 1. Dir., Bureau of Occupational License, Mr. H. B. Whittlesey, 355 State Capitol Bldg., Boise.

ILLINOIS: Chicago, Oct. 1-3. Superintendent of Registration, Mr. Lucien A. File, Springfield.

INDIANA: Indianapolis, June 17-19. Sec., Board of Medical Registration and Examination, Dr. J. W. Bowers, Citizens Trust Bldg., Fort Wayne.

KANSAS: Topeka, Dec. 10-11. Sec., Dr. J. F. Hassig, 905 N. Seventh St., Kansas City.

KENTUCKY: Louisville, Dec. 3-5. Sec., State Board of Health, Dr. A. T. McCormack, 620 Third St., Louisville.

MAINE: Portland, Nov. 12-13. Sec., Board of Registration of Medicine, Dr. Adam P. Leighton, 192 State St., Portland.

MARYLAND: *Regular*. Baltimore, Dec. 10-13. Sec., Dr. John T. O'Mara, 1215 Cathedral St., Baltimore. *Homoeopathic*. Baltimore, Dec. 10-11. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MASSACHUSETTS: Boston, Nov. 12-14. Sec., Board of Registration in Medicine, Dr. Stephen Rushmore, 413-F State House, Boston.

MICHIGAN: * *Lansing*, Oct. 9-11. Sec., Dr. J. Earl McIntyre, 202-4 Hollister Bldg., Lansing.

MINNESOTA: * *Minneapolis*, Oct. 15-17. Sec., Dr. Julian F. Du Bois, 350 St. Peter St., St. Paul.

MISSISSIPPI: *Reciprocity*. Jackson, December. Asst. Sec., State Board of Health, Dr. R. N. Whitfield, Jackson.

MISSOURI: Kansas City, Oct. 29-31. Sec., State Board of Health, Dr. Harry F. Parker, State Capitol Bldg., Jefferson City.

MONTANA: *Reciprocity*. Helena, Sept. 30. *Written*. Helena, Oct. 1-2. Sec., Dr. S. A. Cooney, 216 Power Block, Helena.

NEVADA: *Reciprocity with oral examination*, Nov. 4. Sec., Dr. Fred M. Anderson, 215 N. Carson St., Carson City.

NEW HAMPSHIRE: Concord, March 13-14. Sec., Board of Registration in Medicine, Dr. T. P. Burroughs, State House, Concord.

NEW JERSEY: Trenton, Oct. 15-16. Sec., Dr. Earl S. Hallinger, 28 W. State St., Trenton.

NEW MEXICO: Santa Fe, Oct. 7-8. Sec., Dr. Le Grand Ward, 135 Sena Plaza, Santa Fe.

NORTH CAROLINA: *Reciprocity*. Durham, Dec. 3. Sec., Dr. W. D. James, Hamlet.

NORTH DAKOTA: Grand Forks, Jan. 7-10. Sec., Dr. G. M. Williamson, 4½ S. Third St., Grand Forks.

OKLAHOMA: * *Oklahoma City*, Dec. 11. Sec., Dr. James D. Osborn Jr., Frederick.

OREGON: * *Reciprocity*. Portland, October. *Written*. Portland, Jan. 14-16. Exec. Sec., Miss Lorraine M. Conlee, 608 Failing Bldg., Portland.

PENNSYLVANIA: Philadelphia, January. Acting Sec., Bureau of Professional Licensing, Miss Marguerite G. Steiner, 358 Education Bldg., Harrisburg.

RHODE ISLAND: * *Providence*, Oct. 3-4. Sec., Division of Examiners, Dr. Robert M. Lord, 366 State Office Bldg., Providence.

SOUTH CAROLINA: Columbia, Nov. 12. Sec., Dr. A. Earle Boozer, 505 Saluda Ave., Columbia.

SOUTH DAKOTA: * *Pierre*, Jan. 21-22. Dir., Medical Licensure, Dr. J. F. D. Cook, Pierre.

TEXAS: Austin, Nov. 25-27. Sec., Dr. T. J. Crowe, 918-920 Mercantile Bldg., Dallas.

VERMONT: Burlington, Feb. 11. Sec., Dr. W. Scott Nay, Underhill.

VIRGINIA: Richmond, Dec. 4-6. Sec., Dr. J. W. Preston, 30½ Franklin Rd., Roanoke.

WEST VIRGINIA: Morgantown, Oct. 31-Nov. 2. Sec., Public Health Council, Dr. Arthur E. McClue, State Capitol, Charleston.

WISCONSIN: * *Madison*, Jan. 14-17. Sec., Dr. H. W. Shutter, 425 E. Wisconsin Ave., Milwaukee.

WYOMING: Cheyenne, October. Sec., Dr. M. C. Keith, Capitol Building, Cheyenne.

* Basic Science Certificate required.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

CONNECTICUT: New Haven, Oct. 12. Address State Board of Healing Arts, 1945 Yale Station, New Haven.

DISTRICT OF COLUMBIA: Washington, Oct. 21-22. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

FLORIDA: Gainesville, Nov. 1. *Applications must be on file not later than Oct. 16*. Sec., Prof. J. F. Conn, John B. Stetson University, DeLand.

IOWA: Des Moines, Oct. 8. Dir., Division of Licensure and Registration, Mr. H. W. Grefe, Capitol Bldg., Des Moines.

MINNESOTA: Minneapolis, Oct. 1-2. Sec., Dr. J. Charnley McKinley, 126 Millard Hall, University of Minnesota, Minneapolis.

NEBRASKA: Lincoln, Oct. 1-2. Dir., Bureau of Examining Boards, Mrs. Clark Perkins, 1009 State Capitol Bldg., Lincoln.

OKLAHOMA: Oklahoma City, Nov. 18. Sec., Dr. James D. Osborn Jr., Frederick.

OREGON: Portland, Oct. 26. Sec., Mr. Charles D. Bryne, State Board of Higher Education, University of Oregon, Eugene.

RHODE ISLAND: Providence, Nov. 20. Acting Chief, Division of Examiners, Mr. E. Clyde Thomas, 366 State Office Bldg., Providence.

SOUTH DAKOTA: *Examination*. Yankton, Dec. 6-7. *Endorsement*. Dec. 21. Sec., Dr. Gregg M. Evans, Yankton.

Nebraska June Report

Mrs. Clark Perkins, director, Bureau of Examining Boards, reports the written examination for medical licensure held at Omaha, June 12-14, 1940. The examination covered ten subjects and included 100 questions. An average of 75 per cent was required to pass. Eighty-two candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad.	Number Passed
Rush Medical College	(1938)	1
Creighton Univ. School of Med.	(1938), (1939, 6), (1940, 7)	14
University of Nebraska College of Medicine (1939), (1940, 66)		67

Nine physicians were licensed to practice medicine by reciprocity and one physician so licensed by endorsement from February 8 through July 27. The following schools were represented:

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
University of Colorado School of Medicine	(1938)	Utah
The School of Medicine of the Division of Biological Sciences	(1935)	Illinois
University of Illinois College of Medicine	(1924)	Illinois
State University of Iowa College of Medicine	(1935)	Iowa
University of Michigan Medical School	(1934), (1935)	Michigan
University of Oregon Medical School	(1938)	Louisiana
Baylor University College of Medicine	(1939)	Texas
University of Western Ontario Medical School	(1936)	Michigan

School	LICENSED BY ENDORSEMENT	Year Grad.	Endorsement of
Harvard Medical School	(1933)	N. B. M. Ex.

Kansas June Report

Dr. J. F. Hassig, secretary, Kansas State Board of Medical Registration and Examination, reports the written examination for medical licensure held at Kansas City, June 18-19, 1940. The examination covered ten subjects and included 100 questions. An average of 75 per cent was required to pass. Eighty candidates were examined, all of whom passed. Thirteen physicians were licensed to practice medicine by reciprocity. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
College of Medical Evangelists	(1940)	86
Loyola University School of Medicine	(1940)	82.9
Northwestern University Medical School	(1940)	86.5
Rush Medical College	(1939)	86
University of Kansas School of Medicine	(1940)	79.4
82, 83.7, 84.1, 84.1, 84.3, 84.7, 84.8, 85, 85.3, 85.3, 85.4, 85.6, 86.1, 86.2, 86.5, 86.6, 86.8, 87, 87.2, 87.3, 87.3, 87.4, 87.6, 87.6, 87.7, 88, 88.1, 88.3, 88.3, 88.5, 88.5, 88.5, 88.6, 88.7, 88.7, 88.7, 88.7, 88.8, 88.8, 88.9, 89, 89.1, 89.4, 89.5, 89.5, 89.5, 89.6, 89.8, 89.8, 90.1, 90.2, 90.5, 90.6, 90.6, 90.7, 90.7, 90.9, 91.5, 91.7, 91.9, 92, 92.4, 92.4, 92.6, 92.8, 93.5		
Harvard Medical School	(1938)	86.9
Creighton University School of Medicine	(1939)	85.9
(1940) 81.9, 83.2, 85.3, 86.4		
University of Pennsylvania School of Medicine	(1938)	93.8

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with

University of Wisconsin Medical School	(1932)	N. Dakota
McGill University Faculty of Medicine	(1922)	Penna.

Book Notices

Medical Diseases of War. By Sir Arthur Hurst, M.A., D.M., F.R.C.P., Consulting Physician to Guy's Hospital, London, with the co-operation of H. W. Barber, M.A., M.B., F.R.C.P., Physician-in-Charge of the Skin Department, Guy's Hospital, F. A. Knott, M.D., M.R.C.P., Bacteriologist to Guy's Hospital, and T. A. Ross, M.D., F.R.C.P. Cloth. Price, \$5.50. Pp. 327, with 38 illustrations. Baltimore: William Wood & Company, 1940.

This small volume contains much valuable and practical information. The author lays the greatest stress on functional disorders; of twenty-five chapters fifteen are devoted to functional diseases, eleven to hysteria alone. The importance of the subject may be gathered from the fact that, of 341,025 discharges from the British army, neuroses accounted for 6 per cent. The chief predisposing causes of war neuroses appeared to be the neuropathic and psychopathic inheritance and the previous nervous or mental breakdown. Such men are frequently able to lead normal lives as civilians but are totally incapable of adapting themselves to a soldier's life; in fact the author believes that these "martial misfits" should have never been enlisted. The examining boards were too exclusively concerned with the physical fitness of the recruits.

Of the many hysterical symptoms the most common were paralyses and contractures which followed trivial wounds of the limbs. Hurst insists that these could invariably be prevented by persuasion and reeducation as soon as the condition of the wound made active movement permissible. The hysterical nature of these symptoms was proved by rapid cure with psychotherapy. A temporary organic paralysis may be the starting point of the hysterical paralysis. Hysterical paraplegia may result from the perpetuation of the feeling of weakness in the legs caused by terror. There is a special chapter by T. A. Ross on psychoneuroses of war. Ross points out that the treatment of the anxiety state consists primarily in finding out what the anxiety is about. These patients with psychoneuroses were frequently full of self reproach for having feared. They feared they had been cowards. They dreaded having to go back. They feared very much that they would be sent back before they were well. Hurst and Ross are apparently in agreement as to the treatment of these symptoms. Hysterical symptoms especially could invariably be cured by simple psychotherapy in the form of explanation, persuasion and reeducation. It is pointed out, however, that a "negative reassurance" to a neurotic person does not have the slightest effect on a symptom, whereas the most elementary psychologic explanation will cause all the symptoms to disappear. There is a theoretical distinction between *malingering* and *neurosis*; namely, the *maligner* is fully conscious of what he is doing and the neurotic person is not. The term "shell shock" was much abused in the last war because it was applied to almost any form of neurosis. Hurst has no objection to its use provided one has in mind a condition which has an organic basis for it consisting of the more or less evanescent changes in the nervous system resulting from the concussion caused by aerial compression. It is, however, important to remember that hysterical or anxiety symptoms are frequently superimposed on this organic basis. There is much truth in the author's statement that if it had been generally understood that shell shock was not a method of getting to England there would have been much less of it.

The chapter on soldier's heart is in essence a condensation of the views of Sir Thomas Lewis as presented in the recent edition of "The Soldier's Heart and the Effort Syndrome." The remainder of the book contains brief but informative chapters on trench fever, typhoid and paratyphoid fever, dysentery, epidemic jaundice, tetanus, war nephritis and gas poisoning. The author believes that active immunization with tetanus toxoid of all soldiers proceeding on active service will probably lead to the total disappearance of tetanus as a complication of wounds and passive immunization with antitetanic serum will no longer be necessary. A special chapter by H. W. Barber is devoted to the extremely important subject of skin diseases, in particular scabies and pediculosis. Because of its preeminently practical and authoritative grasp of the problems of military medicine, this volume cannot be too emphatically recommended as compulsory reading for the medical personnel of the examining boards and of the medical officers in active service.

La maladie de Besnier-Boeck-Schaumann: Ses manifestations cutanées, ganglionnaires, pulmonaires, osseuses, oculaires, glandulaires, viscérales, nasales, nerveuses. Par L. M. Pautrier, professeur de clinique des maladies cutanées et syphilitiques à la Faculté de médecine de Strasbourg. Paper. Price, \$2.05. Pp. 341, with 105 illustrations. Paris: Masson & Cie, 1940.

The monograph by Pautrier of Strasbourg presents an interesting and authoritative discussion of the Besnier-Boeck-Schaumann disease. Part 1 deals with the evolution of the modern concept of this clinical entity. Because of its historical importance, Besnier's case of "lupus pernio" is presented in detail. This is followed by the description of sarcoid or lupoid lesions of Boeck. Pautrier himself was first to recognize uveoparotiditis of Heerfordt as one manifestation of the disease. He was likewise first to demonstrate in France a case in which there was pulmonary and lymph node involvement in the absence of cutaneous lesions. It was, however, left to Jorgen Schaumann of Stockholm to demonstrate the essential identity of these apparently unrelated clinical entities. Pautrier is emphatic in stating that it was chiefly due to the labors of Schaumann that what was once considered a rare dermatosis has become recognized as a systemic disease capable of invading any tissue or organ of the body. Part 2 is devoted to the description of the gross and microscopic lesions of the skin, mucous membranes, bones, muscles, lymphoids and blood organs, the respiratory tract, the glands, viscera, and ocular and nervous lesions. The text is profusely illustrated with excellent reproductions of photographs of the author's cases and with photomicrographs of histologic preparations.

In his discussion of the nature and the etiology of the disease the author, while acknowledging our great indebtedness to Schaumann, takes issue with him on a number of points. It appears that this new clinical entity has been rather unfortunate in acquiring a number of eponyms. Pautrier feels that the term "sarcoid" is particularly inept and certainly meaningless in cases not presenting cutaneous lesions. He admits the propriety of calling it Schaumann's disease, but to drop Besnier-Boeck would in his opinion lead to too much confusion in the literature. It is rather surprising that in his extensive discussion as to priority he does not mention Jonathan Hutchinson, whose description of a classic case of lupus pernio preceded that of Besnier by two decades. He is, however, definitely opposed to Schaumann's designation of the disease as benign lymphogranuloma. Schaumann apparently was much impressed with the regular involvement of the lymph nodes and with marked monocytosis, so that he came to consider the disease as a sort of lymphadenopathy. Pautrier's objections are based on the following arguments: 1. The disease bears little if any resemblance to other lymphogranulomas such as Hodgkin's or to venereal lymphogranuloma. 2. It displays predilection not only for the lymphatic tissue but also for the eye, the parotid gland and the hypophysis. 3. The histologic unit is not characteristic of a granuloma. In his microscopic studies the author was impressed with the fact that the histologic unit was always the same no matter where encountered. The epithelioid cells composing it are in his opinion derived from histiocytes; in other words, from reticulo-endothelial tissue. Therefore the lesion is in his opinion a reticulo-endotheliosis rather than granulomatosis. The ubiquity of the reticulo-endothelial system explains the ubiquity of the lesions of this disease. Pautrier further differs with Schaumann on the subject of etiology of the disease. Schaumann believes that it is essentially bovine tuberculosis. Pautrier objects to the tuberculosis theory on the basis of certain microscopic differences, in particular the absence of caseation, the failure to demonstrate tubercle bacilli in stained sections, cultures or animal inoculations, and negative reactivity to large doses of tuberculin. Kissmeyer's and his own statistics show that two thirds of the cases react negatively to tuberculin. Pautrier calls attention to the fact that even among the positive reactors one sees only local skin reaction but never a focal reaction. Pautrier sees a further objection to the tuberculosis theory in a certain antagonism between the two diseases, the absence of tuberculous antecedents in the history of these patients and the fact that when true tuberculous lesions develop in one of these the formerly negative reaction becomes positive, while the sarcoid lesions disappear as soon as true tuberculous lesions appear.

Salben und Salbengrundlagen: Ein Leitfaden für Ärzte und Apotheker. Von Dr. H. v. Czetsch-Lindenwald, Apotheker, Biolaboratorium Oppau der I. G. Farbenindustrie A. G., Ludwigshafen a. Rh., und Dr. F. Schmidt-La Baume, Priv.-Doz., Chefarzt der Hautabteilung der Städtischen Krankenanstalten Mannheim. Mit einem Beitrag: Die Aufgaben der Arbeitsschutzsalben. Von R. Jäger. Paper. Price, 16.80 marks. Pp. 240, with 36 illustrations. Berlin: Julius Springer, 1939.

The difficulties encountered by the authors in their effort to bring the arts of ointment prescribing and ointment making nearer the status of a science are set forth in the preface. Experiments in the laboratory were checked by trials on patients, and the utmost care was observed to make the tests accurate. The authors maintain that the question of ointment bases and their relation to absorption or diffusion of therapeutic agents presents a problem in which not only dermatologists but all physicians should interest themselves. The book is also intended to help the pharmacist, clarifying the borderland relations of pharmacognosy, pharmacology and the knowledge of colloids with pharmacy. It is offered as a bridge between the physician and the pharmacist, explaining to the latter why the physician under certain circumstances employs one ointment and in other cases needs an entirely different one.

The first chapter, after a historical review of the use of ointments, discusses the general bases of salve manufacture, fats, synthetic fats, paraffin hydrocarbons, saturated and unsaturated fatty acids, emulsions, waxes and alcohols. Next the function of ointment is considered, whether it is intended to promote resolution of the inflammation, penetration of the medicament or protection from outside influences. Ointments as carriers of various drugs, such as salicylic acid, mercury and sulfur, hormones, vitamins, bee or snake venom and many other substances are discussed and the use of local anesthetics, disinfectants and dyes in ointments is considered, with the possibility of chemical reactions taking place in the ointment. Warning is sounded against the use of pyrogallol in ointment for the production of imitation tan, which has been practiced in Germany, and the risk of kidney damage and methemoglobin formation is pointed out. The authors, in their laboratory study of the combinations of chrysarobin with various ointment bases, concluded that fats should give better results than petrolatum. Clinical trial in cases of psoriasis showed, however, that the reverse is true and they present this as an illustration of the fact that the conclusions drawn from laboratory experiments and studies of absorption may be wholly reversed by trial in the clinic. Vitamins in salves receive thorough treatment, not omitting vitamins F and H and chlorophyll, though vitamin K is not mentioned. Ointments containing cod liver oil receive attention in four pages.

The chapter on salves containing hormones is of particular interest in the light of the controversy on this question in this country. Nothing is said of the possibility of harm resulting from such ointments used as cosmetics. A striking example of the enthusiasm of European drug houses is granulomosalbe, made in Hungary, said to contain cod liver oil and extracts of testicle, skin, ovary, hypophysis cerebri and thyroid gland. According to Frenkel and Heks (*Terapia* 7:437, 1930) the field of activity of this wonderful ointment corresponds to its complexity. The discussion ends with the remark that in most cases percutaneous hormone therapy should be used to complement the application of ointments containing hormones. Special attention is given salves for the use of the veterinarian, salves for use in the nose or eye, suppositories, the technic of production of ointments, and their testing, packing and preservation.

A pleasant relief from the serious study of ointment construction and use is the short consideration of ancient types of ointment still in circulation, such as those used for witchcraft. The authors quote a Swiss journal's description of an ointment to be applied to the axillae and about the genitalia which is guaranteed to produce pleasant dreams. In the analysis traces of alkaloids were found, which explains the recommendation that the salve be applied to parts secreting alkaline sweat. Evidently the producers later became cautious and reduced the amount of active ingredients to protect themselves. The American cosmetic industry comes in for attention. Navaree is quoted on the constituents of an "eyelash food." Yellow petrolatum perfumed with ethereal oils is completed by the addition of turtle oil. The latter is necessary, no doubt, is the comment,

because of its content of valuable hormones, those that are responsible for the great length of the eyelashes of the tortoise.

The book ends with a plea for more attention to salve bases and salve construction in the daily work of the physician and pharmacist, if they are not intent on being outstripped in this matter by the maker of cosmetics. A simple list of five types of ointment bases is given, from which the physician can choose, depending on the effect desired. An excellent summary sets forth briefly the indications for the various salve types. Apologizing for the fact that not all known ointments have been mentioned, the authors explain that their aim has been to describe types and to mention the most important examples of each type, to avoid complexity.

The appendix, a discussion by R. Jäger of the structure and function of salves intended to protect workmen against irritating substances in industry, is a valuable and practical treatise. The author, while not able to offer any short and sure method of protection against all the cutaneous hazards of industry, suggests a scientific and practical method of attacking the problems as they arise.

The book is a mine of useful information for the physician, the pharmacist and the maker of cosmetics.

Manual of Peripheral Vascular Disorders. By David W. Kramer, M.D., F.A.C.P., Assistant Professor of Medicine, Jefferson Medical College, Philadelphia. Cloth. Price, \$6. Pp. 448, with 126 illustrations. Philadelphia: Blakiston Company, 1940.

The general plan of this book is excellent. There are chapters on symptoms, history taking, physical examination, methods of studying circulation, evaluation of various tests of circulatory function, clinical application of circulatory tests, occlusive vascular disorders of various forms, treatment, vasospastic and vasodilator disorders, hypertension, traumatic vasospasm, gangrene and disorders of veins. Lymphedema is not considered.

While many phases of the subjects presented are admittedly controversial, many statements are made which conflict with the views of accepted experts in the field of peripheral circulation. These statements should not detract greatly from the value of the book. The author writes that claudication is "frequently" relieved by rest. It always is. He states that circulation is normal if pulsations in the dorsalis pedis and posterior tibial arteries are normal, yet there have been reports of thromboangiitis obliterans involving digital arteries when pulsations were normal in the dorsalis pedis and posterior tibial arteries. The statement is made that Negroes do not have thromboangiitis obliterans. That is an opinion contrary to at least one excellent report. Contrary to the author's opinion, bruits are frequently absent in congenital arteriovenous fistula. Also decompensation of the heart is relatively rare when acquired arteriovenous fistula is first recognized. The author implies that cardiac decompensation is always present. He does not support his contention that diabetic "arteritis" is a form of inflammatory occlusive arterial disease; he is inconsistent in classifying "chronic arteritis" under noninflammatory occlusive vascular disorders; he gives no reason for designating arteriovenous fistula as a form of occlusive arterial disease (which it isn't); he confuses temporal arteritis with periarteritis nodosa and he fails to give evidence as to why neurotropic disorders, such as syringomyelia, should be considered occlusive vascular disorders. The statement that thromboangiitis obliterans never has an acute onset neglects reports in the medical literature. It is improbable that "endarteritis obliterans," as described by the author, is a clinical or pathologic entity. Few will agree that peripheral endarteritis is caused by syphilis, and the author has proved only that patients with chronic occlusive arterial diseases occasionally have syphilis. Nothing is said of the desirability of using heparin in arterial embolism. Contrary to the author's statement, erythromelalgia is not always bilateral. The quotation of a classification of essential hypertension lacks accuracy. There is so little in the seven pages on hypertension that they might well have been omitted. There is emphasis on the value of the reaction of the skin to intracutaneous injection of histamine, a test which the author has used extensively, but in many clinics this procedure has been found unnecessary.

Some of the presentation lacks clearness and conciseness and in some parts even the experienced physician may become con-

fused. It is apparent that the subject of peripheral vascular diseases has become too complex for mastery by one person.

The monograph has many virtues. That the author has not supported some particular type of treatment to the virtual exclusion of others, as authors of various monographs on this subject have done, is refreshing. Treatment is emphasized. The chapters which consider methods of studying circulation are generally good. The custom of presenting important points in differential diagnosis in tabular form is desirable. The bibliography seems reasonably complete. This is certainly one of the better monographs on peripheral vascular diseases and is a distinct contribution to the rapidly growing literature on this subject.

Pneumonia and Its Nursing Care. By Herbert K. Ensworth, M.D., Instructor in Medicine, Cornell University Medical College, New York, and Lela L. Greenwood, B.A., R.N., Supervisor of Medical Pavilion, Bellevue Hospital, New York. With a foreword by Russell L. Cecil, M.D. Cloth. Price, \$1.50. Pp. 177, with 44 illustrations. Philadelphia, Montreal & London: J. B. Lippincott Company, 1940.

This booklet contains an account of pneumonia and its modern treatment such as every nurse and intelligent layman should possess. The sections devoted to nursing care are amateurish, and considerable supplementary information would be required by a nurse in the field. It is profusely but not well illustrated, many of the halftones having little instructional value in a nurses' manual. The apparatus is poorly chosen; a single stage regulator is shown. The statement "an oxygen cylinder would last six or seven hours" without reference to the liter flow rate is not helpful. The technic of a nurse collecting sputum with the tent opened shows, unless the motor has been stopped, a wasteful loss of oxygen-enriched air. It is preferable to pass the arm under the skirt of the tent. A thermometer and hygrometer should be in every tent, but the authors neither picture nor refer to them. The principles of tent operation are inadequately discussed, and instructions for measuring the oxygen concentration in the tent are not given. The need for protecting the open box oxygen tent from strong currents of air is not mentioned. A disproportionate amount of space and illustration is devoted to the closed puncture drainage operation for empyema. In most cases of pneumococcal pneumonia this type of operation is inapplicable because there is an abundant pleural deposit of fibrin. The section on diet might have been advantageously expanded. The great importance of adequate salt intake is insufficiently stressed. The advances in practice which will probably come in this rapidly changing field may require another edition, at which time deficiencies, especially in the nursing sections, may be corrected.

Electrocardiography. By Chauncey C. Maher, B.S., M.D., Assistant Professor of Medicine, Northwestern University and the Montgomery Ward Medical Clinics, Chicago, and Paul H. Wosika, M.D., M.S., Instructor in Medicine, Northwestern University and the Montgomery Ward Medical Clinics. Third edition. Cloth. Price, \$4. Pp. 334, with 147 illustrations. Baltimore: William Wood & Company, 1940.

The purpose of this book is to furnish physicians and students not fully trained in cardiology with an introduction to the electrocardiographic method. In presenting the third edition the authors have included consideration of the fourth lead, have utilized the standard nomenclature advocated by the American Heart Association and have correlated their terminology with the usage of everyday practice. Delineation of the basic principles underlying electrocardiography and a concise statement of the clinical aspects of the arrhythmias precede the electrocardiographic portrayal of the various disorders of the heart beat. Succeeding chapters include descriptions of ventricular conduction defects, the changes caused by coronary arterial disease, the effects of drugs, and a summary of the electrocardiographic abnormalities associated with different clinical syndromes. The volume is profusely illustrated by well selected electrocardiograms. Forty-two figures diagrammatically illustrate the physiologic and pathologic aspects of the subject and include additional electrocardiographic examples. Throughout the text the close interrelationship between the clinical aspects of heart disease and the electrocardiographic results is stressed. The authors are to be commended for their repeated caution that "the electrocardiogram is only a part of cardiac diagnostic examination. The history, the objective physical findings, the x-ray, fluoroscopy and laboratory tests all contribute positive or negative information. . . . Overemphasis of the diagnostic

significance of minor defects of the QRS and T waves in an electrocardiogram with other findings normal may lead to unwarranted invalidism. . . . The interpretation of this technical data into clinical evidence is a matter of judicious consideration." The volume is essentially a practical manual for clinicians and as such can be warmly recommended to those who wish to orient themselves in this field.

Diseases of the Digestive System and Food Allergy. By Josef S. Smul, M.D., Assoc. Gastro-Ent., Beth David Hospital, New York. Cloth. Price, \$3.50. Pp. 219. New York: Medical Library Company, 1940.

This curious book was written by a man who seems to have the idea that most diseases of the digestive tract, including cancer of the stomach and amebic dysentery, should be treated with a diet consisting of what he calls anallergic foods. Most curiously he includes among these anallergic foods such items as milk, eggs, wheat, cocoa, tomatoes and melons, which, according to all allergists, are looked on as the worst of offenders. The author believes that what he calls alimentallergy can now replace more than fifty clinical syndromes previously recognized under other names. As one would expect, he furnishes no adequate proof for his astounding doctrines. We suspect the book will be of interest only to collectors of medical curios.

The Diagnosis and Treatment of Diseases of the Peripheral Arteries. By Saul S. Samuels, A.M., M.D., Chief of the Clinic for Peripheral Arterial Diseases, Fourth Division, Bellevue Hospital, New York. Second edition. Cloth. Price, \$6.50. Pp. 372, with 106 illustrations. New York, Toronto & London: Oxford University Press, 1940.

In the present edition this monograph has been greatly enlarged. New chapters have been added on acrocyanosis, periarteritis nodosa, embolism, cervical rib and scalenus syndrome, axillary vein thrombosis, frost bite, glomus tumor and aneurysm of the peripheral vessels. The number of illustrations has been increased. Thus the book has really become a much more rounded out discussion of peripheral circulatory disturbances; because of their frequency, thrombo-angiitis obliterans and arteriosclerosis obliterans have received most of the space. The clear lucid style of the author makes for pleasant and instructive reading. His experience in this field is obvious. The diagnostic methods are simple and his logic of treatment is sound and safe. Great emphasis is laid on oscillometric readings and on the value of color changes; little value is ascribed to the venous filling time and to the histamine and salt wheals. In the treatment of peripheral vascular disorders the author does not advocate suction and pressure therapy, intermittent venous hyperemia, typhoid vaccine injections, whirlpool baths and contrast baths. Hot sitz baths, diathermy and hypertonic salt solutions are favored. The vasomotor component in organic vascular disease does not play an important part in the author's opinion. Sympathetic ganglionectomy and crushing of peripheral nerves are not indicated in the organic vascular disorders. Even in Raynaud's disease, sympathectomy occupies a small place in the author's methods of treatment. This monograph is an excellent account of the author's methods of diagnosis and therapy. As such it is interesting and instructive reading for those who are especially interested in this field. While the subject material has been greatly extended compared with the first edition, it still lacks a wider concept of peripheral vascular disease and hardly covers the achievements of other workers. The general practitioner will not find it a review of the latest developments.

La costituzione della donna e la lotta contro i fattori di sterilità. Atti della 1ª settimana medica internazionale di Salsomaggiore (29 agosto - 4 settembre 1937—A. XV). Pubblicati dalle RR. Terme a cura del Prof. V. de Biasi, docente di Clinica ostetrico-ginecologica nella R. Università di Genova. Paper. Price, 65 lire. Pp. 788, with illustrations. Rome: Luigi Pozzi, 1938.

This work is a compilation of articles presented by various European gynecologists at the international medical convention at Salsomaggiore, Italy, in September 1937. It discusses the subject from an etiologic and therapeutic standpoint. These meetings were encouraged by the Fascist government, whose Duce believes "that strong and fertile human beings are more important for a nation than bars of gold in the treasury." A special emphasis is made of the importance in maintaining a balanced psychoneuro-endocrine system to avoid genital insuf-

fiency. Throughout the work emphasis is likewise placed on the therapeutic value of the Salsomaggiore waters in augmenting endocrine treatment. A classification of the various waters, the different modes of applying this treatment and the rationale of their action are stressed. In a discussion of sports on the maternal function, the author concludes that moderate and sensibly practiced sports increase rather than impair woman's fecundity. The articles add little to the subject of sterility. Considerable repetition as well as a noticeable lack of data and illustrations are apparent.

Les jours de l'homme. Par le Docteur Besançon. Paper. Price, 15 francs. Pp. 149. Paris: Vigot Frères, 1939.

In this essay on longevity the author, an octogenarian, discusses the problem from various angles and comes to some startling conclusions. Four factors are responsible for longevity: (1) continuous flow of sex hormones, (2) mental activity, (3) transmitted diseases and (4) heredity. Mental activity, he says, is necessary for rejuvenation of the brain cells. Many priests, physicians, writers and other intellectuals live long, and more men than women reach old age because brain work required by their profession renovates their hormones. As to the third factor, two thirds of the entire medical field is covered by two groups of diseases: (1) diseases of species, chiefly of an infectious origin, and (2) diseases of individuals, mostly of a nervous character, transmitted from the father to his descendants and represented by a long array of such conditions as eczema, asthma, migraine, dyspepsia, nervous diarrhea, hemorrhoids, lithiasis and diabetes. If such functional diseases persist, longevity may be expected because the patient pays in small instalments his debt for the privilege of living long. It follows that such ailments should not be suppressed, because if they are exterminated the patient may share the fate of his disease. The essay ends with a eulogy of physicians. Malgaigne used to give the following advice: "If your son is intelligent, make an internist out of him; if he is stupid let him be an obstetrician, and if he has no brains but has a manual skill, train him in surgery." Most of the authors' conclusions and remarks do not require comment; they resemble an issue of Tonics and Sedatives.

Tomography. By J. B. McDougall, M.D., F.R.C.P., F.R.S.E., Medical Director, Preston Hall, Maldstone, Kent. Cloth. Price, 21s. Pp. 73, with 110 illustrations. London: H. K. Lewis & Co., Ltd., 1940.

The author has attempted to demonstrate the value of tomography in the diagnosis of pulmonary tuberculosis. Those not familiar with the term will appreciate the explanation that tomography is intended to indicate sectional radiography. It has otherwise been described as planigraphy, stratigraphy and laminagraphy. One author has referred to the instrument for making tomograms as an "x-ray focusing machine." In other words, it is a method whereby the parts to be examined may be studied at previously determined depths. The author argues that tomography is superior to the stereoscopic method. Numerous illustrations illuminate the work, which is in atlas form. The author is not very convincing in his attempt to minimize the value of the stereoscopic method in pulmonary tuberculosis. In certain cases tomography seems to have definite superior value.

Diesel Engines Underground. 1: Composition of Exhaust Gas from Engines in Proper Mechanical Condition. By John C. Holtz, L. B. Berger, M. A. Elliott and H. H. Schrenk. United States Department of the Interior, Bureau of Mines. Report of Investigations 3508. Paper. Pp. 48. Pittsburgh, 1940.

The use of internal combustion engines in underground mining operations presents several interesting problems involving safety and health. This study deals with the nature of the exhaust gases from Diesel motors. These gases may be hot enough to ignite inflammable atmospheres in mines and contain definitely toxic constituents. Variations in use result in changes in the nature of the exhaust gases, but even under optimum conditions of speed, power output and fuel-air ratio, sufficient quantities of carbon monoxide, carbon dioxide, the oxides of nitrogen and aldehydes are produced to make ventilation necessary.

Les pneumolyses chirurgicales dans le traitement de la tuberculose pulmonaire. Par Jean Chenebault. Paper. Pp. 473, with 42 illustrations. Paris: Librairie Louis Arnette, 1939.

The title might be freely translated to read *My Experiences with Extrapleural Pneumothorax, a Review of Over 150 Cases.* If this were the title it would tell exactly what the book is about. Chenebault prefers the term pneumolyses to extrapleural pneumothorax and further distinguishes between two types: the parapneumolyses, which correspond to what we call extrapleural pneumothorax, and telepneumolyses, which correspond to the procedure employed in doing an apicolyses according to Semb. The entire subject is discussed: the history, through anatomy, pathologic anatomy and technic. The last part of the book deals with a report of 115 cases of extrapleural pneumothorax, twenty-one cases of extrapleural pneumothorax associated with thoracoplasty and thirty-seven cases of "telepneumolyses" associated with thoracoplasty. The book is written in French. It is well written and readable. The final chapter sums up the author's opinion on the entire subject. There is a good bibliography. The book should be on the shelf of any one making a study of the collapse treatment of tuberculosis.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice: Fraudulent Concealment as Tolling Running of the Statute of Limitations.—The plaintiff brought suit for malpractice against the three physician defendants in December 1935. He alleged, essentially, that (1) in operating on his wife in 1930 they left two sponges in her abdomen, (2) they allowed her to leave the hospital about fifteen days after the operation while she still had an elevated temperature, without informing her or him of the presence of the sponges and without giving any instruction as to further treatment, and (3) the patient suffered continuously thereafter, necessitating another operation in June 1935, when sponges were discovered in her abdomen and were removed. The plaintiff filed three different amended petitions, the last one in 1938. In the last amended petition he alleged for the first time that the physicians during the operation in 1930 and at all times thereafter knew of the presence of the sponges in the patient's abdomen and fraudulently concealed from him and from the patient their presence and the necessity for removing them. Each physician, in separate answers, took exception to the third amended petition on the ground that it was barred by the applicable two year statute of limitations. They claimed that the plaintiff's cause of action based on malpractice had accrued more than two years before the commencement of the suit and that the cause of action based on the alleged fraud of the defendants had likewise accrued more than two years prior to the first filing of any allegations charging fraud. The court sustained the exceptions and dismissed the suit, and the plaintiff appealed to the court of civil appeals of Texas, Waco.

The plaintiff contended that the action of the trial court was in error, arguing that (1) the two year statute of limitations could not be regarded as running against him until such time as he could reasonably be charged with knowledge that the sponges had been left in his wife's abdominal cavity; (2) the physicians' failure to inform him or his wife of the presence of the sponges in the latter's body tolled the statute of limitations until such time as the presence of the sponges was discovered or should have been discovered, and (3) the charge of fraudulent concealment, contained for the first time in his third amended petition, did not constitute a new and independent cause of action. But, said the court of civil appeals, by the apparent weight of authority a physician's failure to remove a sponge before closing an incision is negligence as a matter of law. Generally the statute of limitations commences to run in such a case as the instant one from the time the duty owing to the plaintiff is breached by the wrongful or negligent act of the defendant, even though the plaintiff is ignorant of the existence of the cause

of action or even though damages are not sustained until after the commission of the tort. But if, as the plaintiff alleged, the defendants in this case knew at the time and continuously after the incision was closed that sponges had been negligently left in the patient's abdomen, and if they discharged her without disclosing the situation and without suggestion or advice as to further treatment, the statute would have been tolled until the fraud was, or could by the exercise of reasonable diligence have been, discovered. Consequently, the trial court should have heard evidence to enable it to determine whether or not there had been a fraudulent concealment, as was alleged by the plaintiff. While the fraudulent concealment of a cause of action by a defendant will prevent the bar of the statute of limitation if the plaintiff in the exercise of ordinary diligence fails to discover the existence of a cause of action, fraudulent concealment of a cause of action is not in itself a cause of action separate and apart from the underlying malpractice. The fraudulent concealment merely estops the guilty party from asserting or relying on the defense of limitations until his fraud is, or by the exercise of ordinary diligence could have been, discovered by the plaintiff. If, continued the court, such a situation existed in the instant case, the plaintiff's cause of action may have appeared to be barred at the time he filed his suit, but it was not in fact barred if the defendant physicians were estopped to rely on the defense of limitation because they had fraudulently concealed the cause of action. Whether it was barred in fact will depend on the testimony which may be presented at a future trial.

For the reasons above stated, the court concluded that the trial court had erred in sustaining the exceptions, and accordingly it reversed the judgment of dismissal and remanded the cause for a new trial.—*Thompson v. Barnard (Texas)*, 142 S. W. (2d) 238.

Malpractice: Liability for Injury to Patient from Nurse's Operation of Fluoroscope.—The plaintiff was referred by her attending physician to the defendant physicians for fluoroscopic examinations. The fluoroscope owned by the defendants was one manufactured by the defendant Black Company. On Jan. 19, 1937, the plaintiff, as she had done preparatory to examination on six prior occasions, stepped up on the foot rest of the fluoroscope and placed her back against the fluoroscopic table which was in a perpendicular position. A nurse employed by one of the defendant physicians, by means of a switch, turned on the electric current which was supposed to cause a system of gears to tilt the table backward so that the plaintiff would lie on it in a horizontal position. While the apparatus was being so operated a pin in the gear system broke because of crystallization and, although the defendant nurse turned the switch in the opposite direction in an attempt to reverse the movement of the apparatus, the table continued to move backward rapidly beyond the horizontal position. The plaintiff was thrown backward off the table, striking her neck and shoulders against the wall and floor. She sustained injuries, to recover damages for which she brought suit against the defendants, the two physicians, the nurse and the manufacturer. From a judgment of the trial court in favor of the defendants, the plaintiff appealed to the district court of appeal, first district, division 2, California.

The plaintiff based her case on the theory that the doctrine of *res ipsa loquitur* was applicable. She contended that, since she had shown that the fluoroscopic apparatus which had caused her injuries was under the management of the defendants and that the accident was one which would not have happened ordinarily if those who managed the use of the apparatus had exercised proper care, an inference arose, in the absence of an explanation by the defendants, that the accident had been caused from their lack of proper care. The district court of appeals, however, was of the opinion that, assuming that the doctrine of *res ipsa loquitur* was applicable, the plaintiff had adduced no evidence which would have supported a verdict in her favor. The court could not agree with her contention that the defendant nurse was incompetent to operate the fluoroscopic apparatus. The nurse's undisputed testimony showed that she was competent and that she had had several years of experience in operating a fluoroscope. With respect to the plaintiff's claim that the nurse had no license to operate a fluoroscope the court pointed out that she had failed to indicate what license a person needs

to operate a fluoroscopic table, a barber chair or any other tilting chair. In operating the switch the nurse committed no act of negligence because, as the evidence disclosed, after the pin broke the table was out of control and its motion was unaffected by any movement of the switch. In the judgment of the court, the plaintiff had failed to prove that the defendants were negligent.

Also, continued the court, assuming that the doctrine of *res ipsa loquitur* was applicable, any possible presumption in favor of the plaintiff was rebutted by evidence introduced by the defendants. They showed that the fluoroscope used had been purchased from a reliable manufacturer only eight years prior to the date of the accident; that the apparatus was of standard make; that many such machines were in use in California and elsewhere and had been used for as long as twenty-five years, and that the fluoroscopic table in question had been used daily and at frequent intervals had been oiled, inspected and repaired. The defendant physicians, said the court, were required to exercise only reasonable care to protect the plaintiff, an invitee, from injury by making ordinary examinations of their equipment. In making a proper examination the defendants were not required, as the plaintiff contended, to go to such lengths as to cause the gear box of the apparatus to be taken off from time to time, the gears removed and the pin taken out of its socket and subjected to the roentgen ray to detect any possible crystallization. Prior to the moment of the accident, the defendants had no notice of any defect in their apparatus because nothing had occurred to indicate that the pin had become weakened or worn. In the judgment of the court, latent defects which are either concealed in defective workmanship or are incidental to ordinary wear and tear of usage are among those casualties which no man can avoid without the exercise of that extraordinary care and vigilance which the law does not impose.

Accordingly, the district court of appeal affirmed the judgment in favor of the defendants.—*Johnston v. Black Co. et al. (Calif.)*, 91 P. (2d) 921.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- Notes on Some Recent Books on Psychoneuroses and Minor Psychopathies. W. C. Alvarez, Rochester, Minn.—p. 346.

Management of Acute Cholecystitis.—Berk presents arguments advanced by the group who regard acute cholecystitis as an immediate surgical emergency and the group who contend that operation should be delayed until the acute stage has subsided. He concludes that: 1. Acute cholecystitis is usually dependent on an obstruction to the outlet of the gallbladder with interruption in the blood supply to the organ. In more than 92 per cent of cases the obstructing agent is a calculus. Secondary infection of the ischemic areas may be present. 2. Acute cholecystitis is a dangerous condition. Under conservative treatment about 25 per cent of the patients will get worse. Complications such as empyema, gangrene, perforation of the gallbladder and generalized peritonitis occur frequently. 3. There is no dependable correlation between the severity of the clinical manifestations and the severity of the disease. It is impossible to predict the outcome. 4. Statistics show that the mortality is great among the "early" operations done after the symptoms have been present for forty-eight hours. Operations done within forty-eight hours have had the lowest mortality rate. Unfortunately few patients reach a hospital within this interval. 5. It is inadvisable to operate on every patient seen within this time as many diagnoses will be wrong. 6. Patients and the disease vary widely and the

treatment must be individualized. 7. A plan of procedure which has been employed successfully in the management of patients is as follows: immediate hospitalization and immediate operation when perforation and peritonitis are present and conservative treatment, if the condition permits, for twenty-four or thirty-six hours followed by operation if the general condition does not improve; a conservative attitude is maintained if improvement is noted.

Pernicious Anemia: Erythrocyte Response to Treatment.—Riddle points out that Minot and his associates, soon after their discovery of the therapeutic effectiveness of liver in pernicious anemia, recognized certain quantitative relationships between the erythrocyte count before treatment, the dose of liver employed in treatment, the number of reticulocytes which appeared early in remission, and the increase in the erythrocyte count. They were impressed particularly by the importance of the large number of reticulocytes in the blood in the first phase of the remission following liver therapy, and they and others devised mathematical equations which represent the numbers or percentage of reticulocytes which may be expected to appear in individual patients with pernicious anemia adequately treated. Although these standard reticulocyte equations have proved useful their value has been disputed, particularly by Murphy. Riddle cites Murphy to the effect that rise in the erythrocyte count would be a far simpler method of evaluating the treatment than the reticulocyte response, if the expected erythrocyte increase were expressed in as simple and as accurate form as the standard reticulocyte equations. The author studied a large number of remissions to determine the quantitative relationships between the rate of erythrocyte increase and the erythrocyte count before treatment. From data of 523 patients with pernicious anemia satisfactorily treated, the average weekly increase in the erythrocyte count at the end of two weeks of treatment was found to bear an inverse relationship to the erythrocyte count before treatment. This relationship is expressed in the equation $I = 0.78 - 0.174E_0$, where I is the average weekly increase in the erythrocyte count after two weeks of treatment and E_0 the

erythrocyte count before treatment expressed as millions of erythrocytes per cubic millimeter of blood. This equation is suggested as a standard for measuring the relative effectiveness of treatment in pernicious anemia. Observed values equal to or greater than those obtained from this equation indicate adequate treatment. Observed values less than those calculated from the equation indicate inadequate treatment. The existence of various complicating factors such as concurrent disease, transfusion or hemorrhage in association with pernicious anemia invalidate the use of this standard.

Complete Occlusion of Abdominal Aorta.—According to Gross and Philips, complete occlusion of the aorta at its bifurcation has been associated clinically with a well delineated group of symptoms. The classic syndrome is one of acute onset with severe pain and loss of sensation in the legs, absence of arterial pulsations and rapidly progressive ascending gangrene of the lower extremities with fatal outcome. In a study of the clinical course of patients in whom, at postmortem, complete obstruction of the aorta was found at its bifurcation, the authors have found that this clinical picture is not constant. They present seven cases of complete occlusion of the aorta at its bifurcation, observed among 5,350 necropsies. Of these, four were patients with atherosclerosis of the coronary arteries and aorta, two with diffuse vascular disease involving the venous system and one with chronic rheumatic cardiovalvular disease, auricular fibrillation and a ball-valve thrombus of the left auricle. The classic clinical picture usually associated with complete occlusion of the aorta at its bifurcation occurred in only one of the first group of four. In another of this group there was nothing in the clinical course to suggest involvement of the aorta but at postmortem the bifurcation was completely occluded by an old gray thrombus. Of interest in the other two is the rapid progress of gangrene with speedy involvement of the opposite extremity. In the two cases with diffuse vascular disease, the aortic involvement seemed to be a mere incident in the course of a progressive disease involving the entire arterial tree with an arteritis in one and venous involvement in the other. The last case resembles in almost every detail the cases described in the literature in which complete occlusion at the bifurcation of the aorta occurred as a complication of chronic rheumatic heart disease with arrhythmia and intracardiac thrombi. The differentiation of embolism from thrombosis as a cause of occlusion of the aorta is difficult. Welch thought that a decision as to the existence of one or the other is often guesswork. Neuhoof pointed out that the mode of onset does not indicate whether one is dealing with embolism or thrombosis, since thrombosis may set in with severe acute symptoms and embolism may produce only intermittent claudication for a long time or no symptoms depending on the size of the vessel and the collateral circulation. The authors think that the departure from the classic clinical syndrome in six of their seven cases were probably due to (1) differences in the rate of progression of the occlusion, (2) the presence of an adequate collateral circulation and (3) subsequent development of a more efficient anastomotic circulation.

Thiochrome Reaction and Thiamine Deficiency.—Borson outlines a modification of the thiochrome reaction of Jansen which provides an easy, rapid and accurate method for the chemical assay of thiamine (vitamin B₁) in urine. Subjects taking a diet adequate in thiamine excrete from 100 to 300 micrograms of thiamine daily. Of a standard oral test dose of 0.1 mg. per kilogram of weight from 8 to 10 per cent is excreted; most of the excess is found in the first five hours. The utilization of thiamine supplements depends in part on the degrees of absorption and excretion; large oral doses are incompletely absorbed and large parenteral doses are rapidly excreted. Therefore small frequent doses are utilized most efficiently. Excretion reflects intake with great sensitivity, even slight degrees of subsaturation being easily detected. The extent of deficiency may be estimated by determining the number of test doses required for the excretion to rise to normal. In patients with severe thiamine deficiency the total amount required for the excretion to become normal was tentatively estimated at about 100 mg. Evidence is presented that thiamine is a *nonthreshold* substance. Diuresis may wash out a considerable amount, thus contributing to the development of deficiency. The excretion in diffuse liver disease may be much higher than normal. This is interpreted as evidence that the ability to phosphorylate thiamine for utilization and storage is impaired. Moderate deficiencies found in patients with thyrotoxicosis despite diets containing fair amounts of "protective foods" may be explained by the increase in the metabolic rate and the consequent increase in the thiamine requirement. Several patients with "neuritis" of uncertain origin, having significant deficiencies, experienced definite relief after thiamine feeding. This indicates that thiamine deficiency played a part in the etiology, although typical thiamine deficiency disease was not present. Marked subsaturation occurred in 50 per cent of patients with multiple sclerosis and 29 per cent experienced definite symptomatic improvement after the oral administration of thiamine. The deficiency probably was secondary as the primary disease was not influenced by the treatment. Deficiencies were found frequently in patients with dorsolateral sclerosis and miscellaneous diseases of the central nervous system. Eighty per cent of patients with central nervous system syphilis were found to be undersaturated with thiamine; 58 per cent were definitely improved following pure thiamine therapy. There appears to be a definite indication for thiamine as a therapeutic measure in tic douloureux. Long-continued administration may be necessary in some patients before improvement will begin. Thiamine feeding was curative in a patient with nonspecific diarrhea, who also recovered from an idiosyncrasy to milk. Thiamine deficiency was frequent in patients with mild degrees of chronic disease of various types. Symptoms which are attributed to the primary disease or to "functional" disorders may be present in these patients and, because the classic picture of deficiency disease is absent, diagnosis can be made only by the therapeutic test. By estimating

the urinary excretion, asymptomatic deficiencies can be readily discovered and the test placed on a sounder basis in the diagnosis of deficiencies associated with symptoms.

Sulfanilamide for Chronic Ulcerative Colitis.—Collins appraises the use of sulfanilamide in the treatment of thirty-three cases of ulcerative colitis, azosulfamide in five and azosulfamide subsequent to sulfanilamide in six. The type treated corresponds to that described by Bergen and Buie as "thrombo-ulcerative colitis." The process was diffuse, inflammatory, destructive and hyperplastic, seen at proctosigmoidoscopic examination, while x-ray examination showed it to extend toward the colon. Sulfanilamide was given by retention enema not exceeding 45 grains (3 Gm.) in twenty-four hours. If the drug is well tolerated it is used for from ten to fourteen days and then on alternate weeks for two or three months with an interval of rest of from one to three months after each course, depending on the clinical course and the results. The enemas are given four times a day but not close to mealtime because of the gastrocolic reflex. Because of the tendency of the disease to recur it is important to use the drug in intermittent courses even after there is no evidence of activity. Since azosulfamide became available, its lower toxicity to sulfanilamide has been established and it has been given only by mouth, a total of 75 grains (5 Gm.) in five divided doses in twenty-four hours. The initial period of use and its intermittent use thereafter are similar to that of sulfanilamide. With continued improvement the daily dosage is reduced and the periods without the drug are lengthened. A complete and continued remission has occurred in eight, or 60 per cent, of thirteen nontoxic cases. In several instances it has lasted over more than two years. In ten (76 per cent) sulfanilamide was considered valuable and was the only treatment used. Further sulfanilamide proved to be of significance in producing favorable responses in fifteen of twenty-six nontoxic and toxic cases, or 57 per cent. Death occurred in four instances subsequent to the use of sulfanilamide. All four patients had extensive, if not irreparable, damage to the entire colon and were severely toxic at the time of admission. Multiple perforations of the colon were found at the time of operation in two patients; the third patient was 76 years of age and died after an operation for prostatic obstruction. Sulfanilamide was administered to the fourth patient for only six days. Ileostomy has been performed on three other severely toxic patients after sulfanilamide therapy failed. In combining these three cases with ten toxic cases in which medical management was employed, a remission attributable to sulfanilamide occurred in only four, or 30 per cent, of this group. Sulfanilamide has a place in the treatment of chronic ulcerative colitis and should be considered an adjunct to the usual forms of treatment and not as a specific remedy. It has proved of greatest value in the early nontoxic stage of the disease.

Purpura from the Arspenamines.—Falconer and his co-workers studied the effects of arspenamines on seven patients who had toxic reactions accompanied by thrombopenic purpura following arspenamine therapy. These patients have submitted

to further injections, reproducing experimentally their attacks of purpura and affording an opportunity to study the effects of oral and parenteral administration of vitamin C on their sensitivity. Six of the patients were known to be sensitive to nearsphenamine and only one to bismarsen. The previous reactions of these patients following each administration of nearsphenamine or bismarsen varied from almost no symptoms in one to marked prostration, nausea, vomiting, rapid pulse, chills and malaise followed in each instance by thrombopenic purpura. Up to this time no vitamin C had been administered. The diet of each patient was inquired into carefully and the intake of vitamin C of only one patient was deemed inadequate. The amounts taken and the intervals during which the patients took vitamin C in crystalline form as ascorbic acid orally and intravenously varied considerably. It was impossible to standardize the sensitivity reaction to a given amount of the arspenamine preparation causing a reaction. The variation of the reaction to different amounts of the drug was marked in the same patient at various time intervals. Variation in the different patients of the series was considerable and appeared as a distinctly individual characteristic. At no time and in no patient was there any appreciable modification of sensitivity reaction during or after the administration of vitamin C. An increase in severity of the reactions after administration of vitamin C in certain of the patients was probably due entirely to increased sensitivity as the result of previously administered arspenamine.

Gonorrheal Septicemia and Endocarditis.—Davis believes that a discussion of gonorrheal septicemia and endocarditis is timely because the condition apparently is not uncommon. The diagnosis is either missed or not made until after death at post-mortem examination and because fever therapy, sulfanilamide and its derivatives are means with which the infections may be combated. The data of fourteen cases, with four recoveries, are reported. Thirteen cases were thought to be endocarditis and one a pericarditis. Two of the patients were seen by the author. The patients who recovered were not proved definitely to have gonorrheal septicemia, but the author gives the following fourteen points which in his case he believes should substantiate such a diagnosis: a positive gonococcus complement fixation test, no petechiae, varying heart murmurs from day to day, no change in conduction time of the heart as would be expected in a rheumatic infection, indication after bouts of pneumonia that the invading organism was sensitive to heat, fluid removed from the cavity in the chest cloudy and apparently sterile (similar observations are made in gonorrheal pleurisy), a history of a severe previous attack of gonorrhea and recent alcoholic and sexual excesses, recovery following multiple blood transfusions and Corbus-Ferry filtrate therapy, five attacks of pneumonia which was probably embolic, the presence of jaundice probably due to hemolysis, a palpable spleen, gallop rhythm on three occasions, severe abdominal pain (probably embolic in character) for which an exploratory operation was performed and evidence of renal infarct. Death in this disease is often of renal origin. The diagnosis is simple in those cases in which the acute disease follows trauma to the urethra in the course of therapy for acute gonorrhea. The author believes that if his foregoing observations are kept in mind an earlier diagnosis may be made, which will prevent useless major operations and explorations of the chest and will hasten the patient's recovery. If sulfanilamide or fever therapy could be used early in the disease, the mortality could be much reduced. A study of the data reveals (1) the difficulty in establishing a definite diagnosis, which is often not made until after death, (2) the frequent occurrence of pneumonia, (3) the infrequency of petechiae and the peculiarity of the cutaneous lesion, (4) the difficulty attendant on obtaining a positive blood culture and (5) the fact that recovery is possible. Accepted forms of treatment seem to be (1) sulfanilamide up to 150 grains (10 Gm.) daily, (2) artificial fever induced by the Kettering hyperthermia, (3) blanketing the patient, thus utilizing the patient's body heat to maintain a fever, (4) multiple blood transfusions and (5) surgical removal of any focus of infection (frequently never found even at necropsy). Sulfanilamide must be given with great caution so as not to deplete the leukocytes and erythrocytes.

Methods for Visual Testing in Schools.—Hitz compared the results of the Snellen chart test, the Betts test and a group of tests (hereafter referred to as the author's tests) consisting of the Snellen chart at 6 meters, the Duane screen test at 6 meters and 33 cm. and the Worth four dot test at 6 meters and 33 cm. The tests were performed by lay examiners on 745 average school children between the ages of 8 and 16. None of the tests were to be considered diagnostic but merely a means of determining which children should be referred to an ophthalmologist for a complete examination. The percentages of those who passed and failed were, respectively, Snellen test 89.7, 10.3; Betts test (the Betts method of grading) 17.4, 82.6; Betts test (the Davenport, Iowa, method of grading) 58.4, 41.6, and his group of tests 55.4 and 44.6. It seems obvious that any test which finds 82 per cent of school children with defective vision is too discriminating and defeats its own purpose. If such were the case it would be more sensible to refer all children to an ophthalmologist and eliminate screen testing. The figures further suggest that the Snellen test alone is missing a considerable number of muscular and fusional difficulties. A comparison of the results obtained with the Snellen test with those obtained with the Betts visual acuity test shows the Betts test to be slightly more discriminating. A comparison of the results of the fusion tests with those of the four dot test reveals that the Betts test again shows the greater percentage of failures. A comparison of the results of the muscle balance tests with those of the Betts test shows that the Betts test reveals more failures. A criticism of the Betts test is that the time consumed in examining the individual person is almost double that with his group of tests. The author believes that his group of tests would seem to strike a mean between the other two tests considered. The tabulated results warrant the conclusion that the tests in present use are either inadequate or overzealous and that a further effort toward the development of standard visual efficiency tests to be used in the nation's schools should be made.

Recovery from Rheumatic Fever Without Cardiac Damage.—This study by Brown and Wolff is based on 175 consecutive unselected cases of acute rheumatic fever, with or without chorea. Only cases in which the diagnosis was clear were included. Following the acute attack they were seen in the cardiac clinic of the outpatient department on repeated occasions over periods varying between four and eleven years, and most of them were seen for the final evaluation of their cardiac status. In arriving at the final opinion, the physical examination, the electrocardiogram, the 7 foot roentgenogram of the heart and the fluoroscopic examination for chamber enlargement were taken into consideration. In this series there were eighty-nine patients who developed or already had valvular damage as a result of rheumatic fever. Patients presenting loud and constant systolic murmurs as the only cardiac abnormality were included in this group. The remaining eighty-six cases were divided into three groups. Group 1 included twenty-one patients who at no time showed murmurs or other evidence of cardiac involvement. Group 2 consisted of twenty-nine patients in whom, at the time of rheumatic activity, murmurs and other evidences of cardiac involvement were present but subsequently disappeared. Group 3 included thirty-six patients who showed a persistent but inconsequential systolic murmur. The present study confirms the known fact that some patients with acute rheumatic fever escape permanent organic valvular damage. The proportion of those escaping permanent cardiac damage is higher in this series (50 per cent) than in any other published series. It is generally believed that, the more severe the infection or the greater the number of recurrences, the more apt is the patient to develop perma-

ment cardiac injury. This belief is not substantiated by the observations here reported. The rheumatic infection in the patients who recovered without permanent heart disease was no different clinically from that in the others. There was no difference in the duration. Of the eighty-six patients who escaped permanent cardiac damage, forty-two had multiple attacks of rheumatic fever. Thus patients who recover without permanent organic heart changes from a first attack seem to have an excellent chance of doing so from subsequent ones. This conclusion is of prognostic and therapeutic significance and makes possible the less rigid restriction of activity of certain patients during subsequent attacks of active rheumatic infection. The final evaluation of the state of the valves must be delayed for several years after an attack of rheumatic fever.

Familial Lumbosacral Syringomyelia.—The appearance at their clinic of two or more members of four different families with trophic changes in the soft and bony tissues of the feet led Van Epps and Kerr to review the literature of similar cases. It is their belief that the various etiologic factors of the syndrome are of the developmental type and that the terms status dysraphicus, myelodysplasia, syringomyelia and trophopathia pedis myelodysplastica all have some basis. They have classified their cases in the syringomyelia group and feel that the term "familial lumbosacral syringomyelia" is the best term. To date there have been reported fifty-four cases, to which the authors

now are adding twenty-seven of their own, making a total of eighty-one cases. They have examined nineteen of the twenty-seven included in this report. Twenty-six of these cases occurred in four families, while in the other case the authors have been unable as yet to establish a familial tendency. Of the nineteen examined cases the feet showed calluses in sixteen, one or more ulcers in seventeen and pain, usually slight, in six. The knee jerks were normal in eighteen, the achilles tendon reflex was absent in twelve and plantar extension was absent in one or both feet in nine. Pallesthesia was impaired or lost in sixteen, hyperkeratosis was present in the hands in two cases, and the skin of the hands was dry and thick in a third case. X-ray examination of the feet showed osseous changes in fifteen cases. These changes were trophic in character—absorption of bone, disintegration of joints, periosteal new bone and pathologic fractures. Soft tissue changes could also be seen. Films of the lumbosacral spine convinced the authors that spina bifida occulta per se is not a necessary part of the syndrome. In four cases there were episodes of severe infection. One case of chronic infection necessitated amputation below the knee. In only one case has there been a possible appearance of the condition in the fourth generation. One family showed an associated case of striate diplegia with athetosis. The sporadic case showed unequal partial Argyll Robertson pupils, primary optic atrophy, and retrobulbar neuritis with slightly constricted fields. This case may be one of tabes, but the authors have included it because they have not seen similar changes in the feet occurring in tabes and because these changes are typical of those in the familial groups. They reach the conclusion that the occurrence of chronic painless ulcers on the feet, especially when associated with x-ray evidence of neurotrophic changes in the bones and joints of the forefeet, should lead to a study of the family history in a search for similar cases. Familial lumbosacral syringomyelia is one of the most frequent causes for such a syndrome. Irradiation of the lumbosacral cord appears to be the best available treatment.

Tuberculous Pericarditis.—According to Heimann and Binder, tuberculous pericarditis is not a rare primary clinical manifestation among Bantu people. Observation over fifteen years in the non-European hospital revealed thirty-one cases; some were of the constrictive type which is amenable to operative treatment and some were only part of a generalized tuberculemia; there were none of the healed constrictive type. The finding of a large "pericardial-shaped heart" in a Bantu justifies a clinical diagnosis of tuberculous pericarditis when rheumatic manifestations and evidence of mitral and aortic disease are absent. Tuberculous root glands were present in all the cases. The tuberculous process was localized to the root glands and pericardium in ten. In six the lungs, pericardium and root glands were tuberculous. Terminal miliary tuberculosis occurred in twelve: in eight following primary root gland and pericardial tuberculosis and in four following primary lung, root gland and pericardial tuberculosis. Pleural effusions were present in fifteen cases, being bilateral in most; in eleven there was either an acute pleurisy or pleural adhesions. Chronic congestion of the liver was present in most with either fibrous, fatty or tuberculous changes. In spite of the short duration of the history, usually between three and six months, the authors believe that the condition is usually insidious in its onset and that these Bantu patients began to notice symptoms only when they became severe. A history typical of congestive cardiac failure was generally given, especially in cases of the effusion type. Usually there was complaint of cough. Hemoptysis occurred in five cases. Seventeen patients complained of abdominal pain, usually localized to the right hypochondrium, and eleven complained of chest pain, usually localized to the precordium. Edema of the legs was observed in eleven, breathlessness in eleven and loss of weight in eleven. The temperature was raised in twenty-two, the respiratory rate in twenty and the pulse rate in twenty-nine. A febrile chart, rapid pulse and breathlessness were found chiefly with pericardial effusions. Most of the patients were poorly nourished; fifteen had an emaciated appearance. Signs of pulmonary tuberculosis were present in only nine patients. The tuberculosis was of the primary clinical type of Riesman (1901). The liver was enlarged and tender in twelve, and eight had ascites. The effusion stage is the easiest one in which to make a clinical diagnosis; the enlarged pear-shaped area of cardiac dullness with an obtuse cardiohepatic angle is the main sign. Death usually occurred in from one to six months after the onset of symptoms. Pericardial aspiration and pneumopericardium improve the prognosis as far as the time of survival is concerned. This is substantiated by the fact that in the only patients who left the hospital the pericardium had been aspirated and in addition pneumopericardium was performed in one. The cause of death is either cardiac failure or, more commonly, miliary tuberculosis, which is common in tuberculous pericarditis. The probable entry of the organisms into the blood stream, particularly in cases in which there is intrapericardial caseation, is by the rupture of a tuberculous follicle into a vein.

- *Tuberculosis of Larynx in Childhood. T. O. Howie.—p. 269.

Tuberculosis of Larynx in Childhood.—Howie looked for laryngeal lesions when examining 159 children, from 4 months to 16 years of age, suffering from pulmonary tuberculosis. Tubercle bacilli were present in the sputum or in the stomach

washings of ninety of these. Thirty-eight of the "open" cases presented tuberculous laryngeal lesions. Tuberculous laryngeal disease was present in only three cases with sputum or stomach contents negative for tubercle bacilli. It appeared that bovine and human infection is equally prone to produce laryngeal disease. Most of the lesions occur in open cases with cavitation and bronchopneumonic pulmonary lesions. Postmortem examination of specimens confirmed this observation. The youngest child to have tuberculosis of the larynx was an infant of 4 months. He died with multiple lesions in the mastoid, the kidney and the intestine. The lungs showed extensive bronchopneumonic disease. In the early stages of laryngeal involvement there is seldom any indication of its presence. The child makes no complaint of discomfort, pain or hoarseness unless the cords are destroyed or kept apart by the bulk of tissue during phonation. Even when the condition has advanced to the stage of perichondritis of the arytenoid or epiglottis there is no complaint of pain. Dysphagia was not encountered. The tuberculous laryngeal lesions conformed to those seen in adults, varying from a slight "streaking" of one cord to extensive destruction of the larynx, with perichondritis and fetid breath. The presence of some of these lesions was confirmed at necropsy. They were usually located in the posterior part of the larynx, in the interarytenoid area and on the posterior extremity of the cords. The disease usually began with a peaking in the interarytenoid area and was followed by destruction of one or both cords over the vocal process of the arytenoid. A few progressed to the stage of tuberculous papillomatosis. When a lesion developed during the interval of six weeks which elapses between examinations of all children, vocal rest and creosote inhalation have in many instances led to a resolution of the condition. The laryngeal condition runs parallel to the pulmonary condition. If the general condition becomes worse the laryngeal condition likewise gets worse. If marked improvement occurs in the former, as it often does after successful pneumothorax treatment, there is a tendency for the latter to be arrested and in some cases to resolve. Possible routes of infection are discussed. The author believes that the cases reported here provide evidence that laryngeal involvement is the result of direct implantation of tubercle bacilli in the tissues of the larynx.

Fibrin Suture of Peripheral Nerves.—Young and Medawar present a method by which stumps can be held together with concentrated coagulated blood plasma. The method reduces the difficulties of nerve suture and minimizes the disorganization of fibers which is apt to be produced by stitches. It consists in holding the cut stumps together and pouring round them plasma which has been mixed with strong tissue-extract. In from one half to two minutes the plasma clots to a firm jelly which sticks to the nerves and holds the stumps together. The plasma is freely permeable and is dissolved away during the subsequent days, remaining, however, long enough to allow a firm union. The gel formed by ordinary plasma is not sufficiently strong to maintain union under tension, but it can be fortified by dissolving in it sufficient fibrinogen to increase its normal concentration. Cockerel plasma has proved more satisfactory than that of mammals. Blood is withdrawn from the carotid artery through oiled cannulas into large centrifuge tubes. These are packed in ice for ten minutes and then spun. The supernatant plasma is stored in waxed test tubes on ice and keeps for at least six weeks. The animal should be starved for thirty-six hours before. No heparin need be used. The concentration is effected by the precipitation of fibrinogen (with

prothrombin) from part of the plasma and by its re-solution in a smaller volume. The concentration thus concerns only the protein constituents. The method of salting out by half-saturation with sodium chloride is unsatisfactory, because the excess of salt interferes with clotting. Mellanby's method is used, one volume of plasma being mixed with nine volumes of redistilled water and then slowly with from 0.1 to 0.15 volume of a solution of acetic acid in redistilled water containing 1 per cent by volume. The fibrinogen forms a flocculate, which is centrifuged out after standing for five minutes. The supernatant fluid is discarded and replaced with water, which is also taken off with a fine pipet. The fibrinogen may now be either used directly or stored under distilled water at 4 C. It keeps for at least ten days. Before use the fibrinogen is dissolved in plasma—not in saline solution, because in the presence of serum the fibrin clot is stronger and much more stable. For use with rabbit nerves a six times normal concentration has proved satisfactory; that is, one produced by dissolving in one volume of plasma the fibrinogen precipitated from five volumes. The quick and even coagulation of the plasma is ensured by mixing it thoroughly just before application with not more than a tenth of its volume of a concentrated tissue-extract. Chicken-embryo extract in saline solution (2 cc. for a ten day embryo) is satisfactory. The plasma method has been found to give satisfactory junction of the cut sciatic nerve of the rabbit. Little or no plasma penetrates between the cut stumps, and no barrier to regeneration is presented. Microscopic study shows that the junctions made by the plasma method are readily crossed by nerve fibers. It is impossible in any nerve junction to ensure that all the fibers pass straight from the central to the peripheral stump, but in the fibrin junction there is a near approach to this condition, with none of the whorls and deviation of large bundles of fibers, which are unavoidable with stitching unless the epineurium alone is sutured—a difficult achievement with small nerves.

Nerve Regeneration.—Young and his associates point out that Cajal has established that recovery after section of a peripheral nerve depends on the outgrowth of new nerve fibers from the central stump but that there still remains some uncertainty about the contribution made by the peripheral stump. Knowledge regarding the peripheral stump is of importance in deciding on operation; e. g., the advisability of delay before suture, and the possibilities of nerve grafts. That the peripheral stump plays a part in making the junction is shown by experiments in which the nerves are cut and the stumps allowed to remain separate. Such operations have been done on rabbits. The rates of outgrowth observed from the central stumps vary from zero, in cases in which a bulb was formed, to a maximum of 0.4 mm. a day. The average rate of outgrowth was 0.2 mm. a day. This is much slower than the rate found for outgrowths from peripheral stumps, which send out strands at a rate of 0.45 mm. a day, and in some cases 1 mm. a day. The extent of these proliferations from peripheral stumps differs from animal to animal, and the authors have not been able to discover what variable factors are involved. It appears, however, that the Schwann cells grow best when they have some support, such as was provided by leaving a part of the sciatic nerve uncut. When the central and peripheral stumps are left close together with a gap less than about 2 cm., union between them may take place rapidly. The average rate for crossing such gaps was 0.77 mm. a day and the highest rate was 1.3 mm. a day. Though it is impossible to discover what proportion of the outgrowth comes from each of the stumps, there is reason to believe that the greater part comes from the peripheral end. The speed of outgrowth of Schwann cells from the peripheral stump suggests that there may be some accelerating and attracting influence exercised by the central stump on the Schwann tissue growing from the peripheral stump. There is no doubt that Schwann cells, growing mainly from the peripheral stump, can effectively bridge gaps between cut ends. The fact that outgrowth takes place so actively from a peripheral stump emphasizes the importance of the contribution made by the Schwann cells to regeneration, and proper appreciation of this is essential in considering the various types of graft for bridging defects. The difficulty in assessing the value of grafts is partly due to the fact that there has been no quantitative comparison. The authors made such a comparison

by measuring the distance reached by outgrowing fibers after the insertion of grafts of various sorts into the peroneal nerve of the rabbit. The grafts were always pieces of rabbit tibial nerve 2 cm. long and were fixed in place under aseptic conditions with concentrated fibrinogen solutions. After from fifteen to twenty-five days the animal was anesthetized and the length of outgrowth determined by pinching the nerve from a distal point upward until a reflex response was obtained. Grafts of different sorts were placed on opposite sides of each rabbit. The authors made experiments with autografts, predegenerated autografts, homografts, stored homografts and alcohol-fixed homografts. It was found that a fresh autograft provides for the growth of new fibers a medium which is only slightly less satisfactory than a normal peripheral stump. Since it seems that successful regeneration depends on the active contribution of the living Schwann cells of the peripheral stump, it is essential that the graft be treated as a living thing and not pinched with forceps, dried or otherwise maltreated. Fresh autografts provide the most successful results, and predegeneration does not seem worth while. The success of the thin Ballance-Duel grafts suggests that small nerves may make better grafts than large nerves, and a cable graft of several thin strands is probably better than a single thick graft.

- *Influence of Heredity in Allergic Disease: Study of Familial Incidence in 350 Allergic Persons. A. de Oliveira Lima.—p. 379.
Practical Classification of Convulsions. J. Barbosa.—p. 383.

Heredity in Allergic Diseases.—De Oliveira Lima discusses the role of heredity in the development of allergic diseases and reports his observations on familial incidence in 350 cases of allergy in persons of either sex. There was a history of allergy in the parents or relatives of the patients in 289 cases. It was found lacking in sixty-one persons who were classified as patients with specific hypersensitivity not related to heredity. The author found that hereditary allergy may be transmitted by the two or either parent in the same ratio of incidence regardless of the sex of the transmissor parent. The first symptoms of allergic disease develop before puberty in persons with bilateral allergy from both parents and after puberty in those with unilateral allergy from either parent, as well as in those with allergy from specific hypersensitivity not related to heredity. In the group of cases reported by the author genotypic predominated over phenotypic heredity. There was bronchial asthma in 100 cases, migraine in twenty-eight, chronic rhinitis in 180, urticaria in twenty, atopic eczema in thirty-two and allergic disturbances of the digestive tract in twenty cases. Evidence of hereditary transmission of an organ of shock was found in none of the cases. Some persons with a history of bilateral or unilateral allergy in the ancestry had prepuberal allergic children. Allergy in these cases followed the same behavior as that of the condition in adults. None of the persons with specific hypersensitivity not related to heredity had children with allergy. The children in this special group were young and far from the prepuberal age.

*Treatment of Pulmonary Abscess with Alcohol Enemas. S. I. Mazel.—p. 12.

Alcohol Enemas for Pulmonary Abscess.—The good results obtained in the treatment of acute and subacute pulmonary abscesses with intravenous injections of from 20 to 30 cc. of a 10 per cent solution of alcohol in physiologic solution of sodium chloride suggested to Mazel the rationale of administering it by the rectal route. He believed that the alcohol would be absorbed by the inferior hemorrhoidal vein and thus gain direct access to the pulmonary circulation without passing through the liver. The alcohol exerts a bactericidal effect on the early suppurative focus in the lung, stimulates the reticulo-endothelial tissue to the formation of antibodies and assists in obliteration of the formed cavity. The method consisted of a daily preliminary cleansing enema followed in from two to three hours by introduction into the rectum of from 60 to 75 cc. of 10 per cent alcohol in physiologic solution of sodium chloride. The average duration of treatment was from thirty to thirty-five days. After some twenty enemas the temperature, as a rule, fell, the sputum diminished in amount and lost its offensive odor, elastic fibers were no longer present and the general state improved. With further therapy, infiltration and cavities disappeared in roentgenograms. The author reports the results in twenty-nine cases treated since 1937. The duration of the process in twenty-five was from two weeks to five months, and in four from eight to twelve months. Ten patients were cured, eleven much improved, four improved, in two no results were obtained and two died. The author concludes that the rectal method is as effective as the intravenous. The method is most effective in the stage of suppurative infiltration before the formation of a cavity. It is effective in the acute and subacute stage but is of no value in the chronic stage.

- *New Electro-Encephalographic Rhythm in Epilepsy. T. Dalsgaard-Nielsen.—p. 1119.
*Investigations on Vegetative Function in Posttraumatic Dystrophia of Extremities. H. Haldbo.—p. 1124.
Case of Obliteration of Mesenteric Blood Vessel. A. Birch-Jensen.—p. 1128.

Electro-Encephalographic Rhythm in Epilepsy.—Dalsgaard-Nielsen reports three cases of symptomatic epilepsy with a peculiar "1 Hertz rhythm" not previously described, which is characterized by (1) regularity, (2) low frequency: "1 Hertz rhythm," (3) low potential, about like that of a normal fronto-occipital Berger rhythm, (4) typical form, with even slow rise and abrupt fall and (5) derivation from a single focus. In the first case there was evidence of cerebral atrophy at the site of the lead, but the history did not suggest traumatic origin. In the second a traumatic etiology seemed possible and there were clinical signs of pathologic changes in the brain at the site of the lead. In the last case, with certain traumatic origin, ventriculography and operation confirmed the presence of a traumatic brain process at the site of the derivation. The author gives warning that there may be sources of error, and furthermore that this rhythm may originate as a pulsation phenomenon, and says that evaluation of the nature and diagnostic importance of the "1 Hertz rhythm" must await the results derived from further examinations.

Vegetative Function in Posttraumatic Dystrophia of Extremities.—Haldbo's examinations in about fifty cases of posttraumatic dystrophy of the extremities, recent distortions and contusions, also some inflammations, showed vasomotor disturbances and disturbances in the secretion of sweat in all cases. He states that as a rule the disturbances disappeared in from two weeks to two months but that they persisted in cases in which haliteresis, edema and cutaneous changes occurred, and anhidrotic parts may extend and gradually occupy an entire extremity. He stresses the practical value of the perspiration test in the surgical clinic as a simple method which allows vegetative disturbances to be followed and timely treatment to be instituted.

Hygiea

- *Sulcus Superior Tumors. C. G. Ahlström.—p. 1129.
Disturbances in Albumin Content of Blood. H. Malmros.—p. 1134.
Clinical Value of Galactose Test in Hepatic Disorders. T. Hafström.—p. 1137.

Superior Sulcus Tumors.—Ahlström's first patient, a man aged 36 with increasing radiating pain in the upper thorax for about half a year, was shown by x-ray examination to have a shadow in the apex of the right thoracic cavity, together with partial destruction of the second and third ribs and corresponding processes on the right side. Shortly before death complete paralysis of the lower extremities occurred. Necropsy disclosed a tumor belonging to the chest wall, with subapical localization and only slight marginal infiltration of the lung, destruction of the posterior parts of the second, third and fourth ribs and invasion of the spinal column and compression of the spinal cord. Microscopically the tumor was an endothelioma of the pleura. The second patient, a woman aged 60 with increasing pain and numbness in the left arm for several months, had an apical shadow in the roentgenogram extending to the left hilar region, with atrophy and destruction of the upper ribs on the left side. Necropsy showed a scirrhus tumor, corresponding in structure to that in the first case, in the left thoracic inlet, extensive infiltration of the surrounding tissue, destruction of the upper ribs and dislocation of the apex of the left lung by the tumor, which was intimately attached to the pleura and had only slightly invaded the apex. The author says that the term "sulcus superior tumors" is a collective designation for neoplasms which occur in a certain area of the thoracic inlet and that in practice two kinds of these tumors are to be reckoned with, namely apical lung tumors, which make up the majority of sulcus superior tumors, and tumors of the cupola, which are mainly endotheliomas of the pleura.

At the Dawn of Modern Youth in Medicine

VERNE C. HUNT, M.D.

LOS ANGELES

The recent graduate in medicine has arrived at an important period in his career without much thought perhaps of how so many apparent obstacles to his progress could have been devised, and why the exacting program in which he has been engaged should be necessary. On reflection, however, it is obvious that obstacles have not been hastily erected nor has the educational program which he has completed been other than constructively arranged. In the evolution of medical education this has occurred in an orderly fashion.

Medical education in this country began in 1765 with the organization of the College of the Philadelphia Department of Medicine, which in 1791 became the University of Pennsylvania Department of Medicine and in 1909 assumed its present title of the University of Pennsylvania School of Medicine. In 1768 this school granted the first medical diploma issued in America. Since the beginning of medical education in America, about 460 medical schools have been chartered in this country and Canada; today there are only eighty-seven approved medical schools in the United States and Canada. In other words, in 140 years about 370 medical schools have come and gone, for there were but five schools in 1800. Medical education in the United States today is regulated by rules and specifications of the American Medical Association, together with those of the Association of American Medical Colleges and by the requirements of the various states for licensure to practice.

In order that one may understand the reason for rules and definite regulations in medical education, it may be stated that the nineteenth century witnessed the organization of many schools for instruction in medicine which were frank commercial enterprises in design and purpose. The general level of practice of the recipients of certification in medicine by many of these schools was low and the tendency was downward. Early in the last

century less than 10 per cent of the physicians in this country were graduates of medical schools and more than 80 per cent had not attended lectures in a school of medicine. The need for improvement in methods and the elevation of medical education was apparent as early as 1827. In that year delegates from the medical schools and various societies convened and formulated certain recommendations regarding the length of the medical course, and they suggested that Latin and natural philosophy be required preliminary to the study of medicine. The first national medical convention in the United States was held in 1846 for the purpose of advancing the standards of medical education. At the convention the following year the name of the American Medical Association was adopted.

Even though many other agencies have been cooperative and influential in the advancement of medical education, it has been the object of the American Medical Association throughout the years to promote the science and art of medicine as well as the betterment of the public health, and it has pursued with diligence the self-imposed task of elevating medical education. The effectiveness of rules and specifications for medical education as they have been developed and amplified from time to time may be attested by the failure of so many schools to meet the standards for approval. Consequently such schools soon ceased to exist. It is of interest that today relatively few schools approved by the American Medical Association retain their approval through fulfillment of only the minimum requirements. As a matter of fact, most of the approved medical schools of today are strong medical departments of universities with high educational standards.

As medical education has improved during the years, so has the standard of education preliminary to the study of medicine been elevated. In the educational number of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION dated Aug. 26, 1939, it may be noted that a baccalaureate degree is required preliminary to admission to five medical schools in the United

Read before the annual meeting of the staff of the Alameda County Hospital, Oakland, Calif., June 6, 1940, on the occasion of presenting certificates to interns and residents of the hospital.

States, that 60 per cent of the medical schools require three years of college work and that only eleven medical schools accept the minimum requirement of two years of preliminary education which is acceptable to the Council. That the standards of preliminary education have been elevated materially is indicated by data from the Council on Medical Education and Hospitals of the American Medical Association, which discloses the interesting fact that in 1910 only 15.3 per cent of the graduates of medical schools in the United States held baccalaureate degrees whereas, in 1932, 71.4 per cent of the graduates held the degree of either A.B. or B.S. A decline to 66.5 per cent of graduates from the seventy-seven approved medical schools in the United States in possession of a baccalaureate degree has occurred since July 1, 1938.

THE PHYSICIAN AN EDUCATED PERSON

I speak of these matters for the purpose of emphasizing that men and women of medicine today are educated persons. They are educated not only in medicine but in the arts and sciences as well. This is in no wise intended as disparaging to those who have preceded us, for it was not their privilege to enjoy and profit from the great educational facilities of today. The stature of many of those of the past was such that they attained memorable and undying distinction in their achievements without the insignia of one of letters, and unlimited tribute is due those of that earlier period who through their earnestness, integrity and splendid personal characteristics were able to maintain the profession on so high a plane with a foundation so unstable, and to hand down to those who followed a legacy to which they contributed so much more than they had received.

Medicine has advanced so rapidly during the past twenty-five years or thereabouts that the curriculum of the medical school has by virtue of necessity undergone great change. Some years ago an opportunity was provided to obtain under supervision at least some practical experience during the clinical years. The crowding of the curriculum with the requirements of the medical education of today has largely eliminated that opportunity. Practical experience can be obtained now only through internship, residency and what constitutes organized postgraduate training. The University of Minnesota was the first to make practical rectification of this situation in medical education and since 1915 it has exacted a year's internship requisite to the degree of Doctor of Medicine. Thirteen medical schools in the United States and Canada now require the internship for the degree of Doctor of Medicine. One of these, Duke University, requires two years' internship, even though the M.D. degree is granted after completion of the senior year.

Twenty-two states, the District of Columbia, Alaska and Puerto Rico require hospital internship of all applicants for licensure.

It may seem to those who are unfamiliar with the past, and to those who are not cognizant and aware of the magnitude of the science of medicine, that the program of education and training imposed on the aspirant to fellowship in the medical profession is unduly burdensome in educational attainments required, in time consumed and in energy expended. It should be stated that the magnitude of the science of medicine is unlimited, in medicine one consumes all time, medicine commands one's entire effort and energy, and educational attainments of the highest order are essential for even a modest comprehension of all that medicine involves. Medicine is a chosen profession but a profession which accepts only those who are physically, mentally and morally qualified not only to endure its prerequisites but to challenge and engage the problems and responsibilities of its sphere. Medicine likewise rejects those who have ambition without cause.

The recent graduate in medicine has had but one educational highway along which he could proceed with others to attain his present station. There now lies before him a maze of routes diverging from that which he has just traversed and undoubtedly he has experienced some bewilderment in the selection of his future course and has wondered what his ultimate destination in medicine may be. It is during one's youth in medicine that one's individual traits, inherent aptitude, talents, capabilities, natural tendencies and physical, mental and moral characteristics as they have been influenced by what has preceded will take form and mold one as a distinctive individual in medicine. One will proceed in medicine as one has been molded. Fortunate indeed are those who through predilection have chosen a future course, leaving them unencumbered by indecision to pursue their objectives. Indecision and uncertainty on the part of the recent graduate should not be disconcerting, and that an open highway to his own desirable objective, equipped with a conveyance assuring him of easy and comfortable passage, is not immediately visible and available to him should not serve to discourage. Instead, one should be mindful that Pasteur, Lister and others were among the many whose achievements have been notable, epoch making, revolutionary and not infrequently subjected to bitter challenge and that they hewed and hacked their own road through virgin forest. One may say that this was long ago and can no longer occur. The reply is that new roads and by-ways are being driven into the unknown of medicine today and that the achievements in the advancement of medical science of today will be ranked with

those of the past by the future historian. A multitude of opportunities continue to exist in medicine for those of discernment, initiative and the will to do.

POSTGRADUATE TRAINING AND EXPERIENCE

The graduate in medicine today is a sound product of modern education and is better prepared fundamentally in all phases of medicine than were his predecessors to engage the problems and responsibilities; yet, inconsistent as it may seem, the door to the field of active practice has not been flung wide but stands ajar to those who may with courage but without wisdom venture forth. This reflects not on the educational program that the graduate has just completed but is due to the demands of modern practice. Pasteur said "Chance favors the prepared mind." Another has said "The prepared mind is a mind stored with the history and fruits of human experience. It is a mind which has been called upon in the course of its education to deal with problems, now of one kind, now of another. It is a mind fitted to enjoy and to be guided by the spiritual experiences of the human race." An intellectual preparation of the mind occurs while one is engaged and occupied in a formal educational program or curriculum. Maturity of mind occurs only through experience in the subsequent formal and informal activities of human endeavor. Herein lies the necessity for and the value of adequate postgraduate training and experience. The question of what constitutes adequate postgraduate training and experience is immediately in order, and it cannot be answered in a dogmatic fashion or without deliberation.

A period of more or less formal and organized study in hospitals and clinics immediately following the completion of the medical curriculum is the order of the day. The length of time which can be spent in such postgraduate study and supervised experience varies from a minimum of one year's internship to a carefully organized progressive program of approximately seven years in a few institutions, wherein unusual facilities for such training exist or have been organized, with from three to five years constituting the period in many institutions. As to just what type of postgraduate training one may engage in following the internship and where the desired training may be obtained constitutes a problem the solution of which is often extremely difficult. Irrespective of what branch of medicine one wishes to make one's life work, it is generally agreed that the broad foundation gained from a rotating internship provides the most stable footing from which one may progress. One's own inherent talent in a certain direction is perhaps the most important influence. One should aspire to employ one's time and energies in the direction of that phase of medicine to which one has been

attracted and in which one has demonstrated to oneself and to others that one possesses talent. There are many in medicine who have not chosen their sphere wisely, who through inherent deficiencies requisite to the pursuit of certain branches of medicine are totally unfit, but who in another field of medicine might proceed with credit and even bring luster to their names and to the medical profession as well.

Fortunate indeed is he who either during his student days or while engaged in his internship has recognized that within himself there are certain attributes which qualify him peculiarly and particularly in a special branch of medicine. And fortunate indeed is he who during this period has come under the influence of an inspirational preceptor who has recognized a dormant or latent talent and has sparked the mechanism which propels the youth to otherwise unattainable heights in medicine. The necessity for the firing of ambition in medicine is great, and that fire must continue to burn in order that one may progress. This is spoken without reference to any particular branch of medicine. Fire is as essential to general practice as it is to any of the specialties. Work is the center of the circumference of one's life in medicine, and only through the ambitious pursuit of one's work can one continue to enjoy the routine tasks and smile at disappointment. It should be emphasized that, irrespective of the branch of medicine that one wishes to pursue, there are many routine tasks and as many disappointments. It is essential that one develop a philosophy good for all weathers.

GENERAL PRACTICE AND THE SPECIALTIES

Those who choose to engage in general practice must of necessity sacrifice depth of knowledge in favor of breadth. Herrick has said "To the brilliant mind of half a century ago a working knowledge of all the departments of medicine was attainable; today such a progeny is impossible." The field of general practice is broad, but through specialization depth of knowledge has been made available in accordance with modern practice. Specialization in the various fields of medicine provides for proficiency when proper correlation of the specialties and of the specialist exists but inadequately serves when carried to organs or systems of organs with narrowing of vision and loss of the perspective of the organism as a whole.

Those who have chosen to engage in general practice are legally qualified to do so, and their moral qualifications will exhibit themselves as they refrain from attempting the use of methods and the performance of technical procedures in which they have not been trained. Those who aspire to proficiency in a special field of medicine need not sacrifice breadth of medical

knowledge but must attune themselves to the depths of the special field and to the time and energy requisite to the attainment of recognized proficiency. To speak specifically in medicine it is not enough that one know when and how much insulin shall be administered to the diabetic patient; one must know all that is known about the disease, its allied metabolic disturbances and the basic therapeutic principles. It is not enough that one know that the administration of vitamin K and bile salts serves as a specific in the control of the hemorrhagic tendency in obstructive jaundice and in certain other prothrombin deficiency states. It is not enough that one know much of the present in medicine and little of its past. It is not enough if one does not now know or if one does not learn as one progresses the processes through which medicine had advanced. No cursory survey of a subject or of a field of medicine today qualifies one as outstandingly proficient in that branch. There is no short road or circuitous route by which one can arrive at proficiency in any of the specialties of medicine. This is particularly true of surgery and its allied specialties. It is true that the degree of proficiency attained by those who pursue a prolonged period of formal training in surgery is a variable one. Proficiency in surgery depends on many factors. I cannot define them all. The surgeon may become mature but he is never a finished product. To progress he must grow, and to increase his surgical stature requires physical, mental and moral sustenance. *Surgery commands certain attributes which fundamentally are inherent, and without these the seeds of training fall on infertile soil.* One is not born a surgeon, but a surgeon is born with certain inherent qualities which influence those that may be acquired. Postgraduate training may enable one to execute surgical procedures skilfully and under supervision exhibit a tendency to stay a courageous hand, but something more is essential to the proper direction of the mind and the hand of the surgeon. The moral ingredient of man provides the foundation for the rearing of judgment which must guide the surgeon in the utilization of his knowledge and the application of his skill.

To those who aspire to proficiency in surgery or in one of its allied fields I should like to appraise the depths. As no one untrained can successfully explore the depths of the sea, so can no one venture without adequate postgraduate training, and the resultant armamentarium, into the field of surgery with hope to achieve. To define adequate postgraduate training in surgery is not dogmatically possible. However, certain minimum standards have been erected by the American College of Surgeons and by the various American boards for certification of the specialist by which his status may

be recognized. This is all in entire conformity with the ideals of medicine to leave it better than when it was found.

CHALLENGE TO PROGRESS

As one proceeds through life in medicine one will find it of advantage to maintain a progressive spirit, and to progress one cannot with aristocratic detachment go his own way. The fellowship that one can enjoy with his colleagues in medicine provides the stimulation so constantly necessary in an exacting profession. One will find as one proceeds day by day and from one year to another that one's progress is constantly subject to formal, informal, visible and invisible challenge. No two words express so eloquently the significance of that daily challenge in medicine as do those comprising the title of Lloyd Douglas's recent book "Disputed Passage." You at this time have in common with your faculty members and your preceptors only one distinction, possession of the degree of Doctor of Medicine. As to whether you will adorn that distinction depends not only on the height but on the manner of your achievements.

I would repeat that the man of medicine today is an educated man. He is educated not only in medicine but in the arts and sciences as well. It is expected of him, and not unjustly so, that his thoughts, his spoken words and his conduct shall at all times and under all circumstances reflect with honor and distinction on his own inherent capacity, opportunity and privilege to attain the high educational status that qualifies him to receive at the hands of those who are authorized to bestow them the insignia by which he may be recognized as an educated man and a doctor of medicine. The man of medicine who utilizes his premedical education in the arts and sciences not as a springboard to the medical curriculum but as the foundation for the building of a broad culture wherein the spiritual phase of medicine arranges a perspective through which ideals can be appreciated will find happiness and success by his own measure of achievement.

It is my hope as you engage the problems and responsibilities of your chosen profession that you will at all times and under all circumstances perform your professional duties with compassion, unselfishness and honor; that in your work you will always find happiness but will never be entirely content with your progress; that when you have completed your life's work your contributions, humble as they may be, will have served to make the profession of medicine better than one finds it today. It is my wish to leave with you the words of Albert Pike, who said "What we have done for ourselves dies with us, what we have done for others and the world remains and is immortal."

561 Roosevelt Building.

Digests and Reviews

TO THOSE ENTERING THE MEDICAL WARDS

By Dr. A. H. Douthwaite. Slightly abridged from *Guy's Hospital Gazette*, Oct. 22, 1938.

The physical transition from medical school to the wards is of small moment; it is the complete change in the character of work, the acceptance of actual responsibility for sick people and, more than all, the observance of their mental reactions which mark this as an epoch of considerable significance. Those of you who come to us from other schools may be struck by the absence of formality which exists at Guy's. Though subjected to criticism from some quarters, it is, I believe, a desirable feature inseparably linked with the policy of producing men trained to be practical rather than those nurtured on compulsory lectures now rendered an anachronism by a superfluity of textbooks. Rather do we invite you to accompany your teachers in the wards, see the problems for yourselves, ask questions when you will, and argue if you wish. Perhaps you have had mediocre success in the medical school and this has led you to doubt your ability to clear the last fences. Banish the fear. The best clinicians often emerge from such unpromising beginnings.

The next few years will be hard; the days of long holidays are over, for a fortnight out of an appointment is the maximum which can be taken lest valuable experience be sacrificed. The curtailment of time for relaxation is fortunately well compensated for by an infinite variety of enthralling experience.

As to the planning of your studies, accept the fact that last-minute cramming for final examinations is of no use. The subject is too vast for any than gradual absorption, so it is well to follow some plan from the outset. The preliminary clinical period prepares you thoroughly for the routine examination of patients and thus prevents waste of time when you enter the wards. Beds and their human contents are allotted to you, and therewith your share of responsibility. The taking of the medical history is the most important step toward arriving at diagnosis. This is primarily your job and its value cannot be overemphasized, though too often forgotten in a desire to search for physical signs of disease. The ability to sift the relevant facts from matter which obscures can come only with experience. In the meantime bear in mind the value of facts, as opposed to patients' interpretation of them, and of their presentation in a legible and, where possible, schematic form. When writing a report, do so with the thought that on its accuracy may depend the outcome of valuable

research undertaken years later. Whenever possible, examine your patient before he is seen by the registrar and commit yourself to a diagnosis. Progress of the disease, ultimate outcome, treatment given, opinions expressed on diagnosis, should all be entered to make the records of lasting value. Forms are now issued on which you can write down your observations and conclusions, and this should invariably be done. It is the only way to avoid that type of mental dishonesty which leads to brilliant differential diagnoses any one of which can be claimed as a personal success at a later date! This dangerous habit once acquired is difficult to discard. It meets with but scant respect, however, from the relatives of the sick. Mistakes have a high educative value. They snatch one with a jerk from the danger of self complacency.

Probably the best plan of study is to concentrate for the first three months on pathology. This entails, of course, frequent visits to the postmortem room. Given this grounding, symptoms and signs become the natural expression of the disease and their memorizing is unnecessary. Probably the most valuable time of the day for the acquirement of practical knowledge is that which follows the afternoon round. It is then that the house physician performs lumbar punctures, collects blood, taps chests and so on. These procedures should be watched and from time to time you will be given the opportunity of carrying them out yourself. It is now also that special signs referred to in the teaching round can be reexamined and thus fixed in the memory. It should be made a point of pride that within a fortnight you should be able to inspect the optic disks of any patient you may choose. Once the knack has been acquired, and it usually comes quite suddenly after several days of disappointment, it will never be lost. It takes many months to be certain of the normal as opposed to the diseased disk, yet recognition of early change may be of the utmost importance in determining a diagnosis and possibly even in saving a life.

The patients in your beds will confide in you possibly more than in the house officers or staff. To them you are their doctor and from you they will try to get confirmation of their fears in respect of illness, or of suspicions in relation to earlier treatment. An immense amount of mischief is caused by the making of unguarded remarks which can be misconstrued. Their avoidance is doubly difficult in a teaching hospital, where a discussion on the problem is too often carried out within earshot of the patients. We all err unwittingly in this respect, and the

importance of discretion needs reiterating. The fact that a patient can inspect his own report is deplorable and should be remedied.

Attend outpatients when you can. This is the only hospital activity which remotely approaches the conditions which obtain in general practice. The frequent absence of physical signs may be tedious, but precisely for this reason is the experience invaluable in forcing you to rely more and more on history taking. It is an antidote to the poison of mechanized medicine, the virulence of which increases with every new instrumental aid to diagnosis.

Don't live near the hospital until you have to. Knowledge is not in the air; disease is.

Go away for week ends.

Take holidays, abroad if possible, and with anybody who is not a medical student or a doctor.

Be active in the debating society. The ability to stand on one's legs and talk is acquired painfully by many of us. Its value is inestimable.

Insure your life and health, and join a society for protection against possible legal proceedings as soon as you are qualified.

In moments of despondency remember that medicine is the only profession which never provides two days which are alike and in which boredom is a rarity.

THE BROADENING HORIZONS OF MEDICINE

Condensation of an article by Dr. Winfred Overholser, read at the opening session of George Washington University School of Medicine, Washington, D. C., Sept. 25, 1939, and published in Science, Oct 20, 1939.

Many of those present today are taking their first steps along the road which leads to the practice of medicine. The road is difficult. Even those who are present today for the first time have already spent two years or more in college studying premedical subjects. They must spend four years of study in the medical school, after which there will come a period of internship. I am bold enough to question the wisdom of some of the required premedical work. There is a tendency today to require specialism altogether too early and to leave out of the equipment of the medical man what were known in the old days as the humanities. Although medicine has developed almost unbelievably, there are still other things which make life worth living and to which the medical man should not be inattentive. Let us hope that the day is not gone forever when medicine can produce such *littérateurs* as Oliver Wendell Holmes, S. Weir Mitchell, Sir William Osler and Harvey Cushing. I recommend as a decided contribution to a balanced mind the development of hobbies to which one can occasionally flee from the practice of medicine.

ATTRIBUTES OF A PHYSICIAN

In the midst of a cynical world it is well to reaffirm one's faith in such a thing as altruism, the desire to serve one's fellow men. I may be pardoned a quotation by referring to the tribute paid to the physician by Robert Louis Stevenson. The physician, as a rule, he comments, stands above the common herd, shares as little as any in the defects of a period and most notably exhibits the virtues of the race; he says of the physician: Generosity he has, such as is possible to those who practice an art, never to those who drive a trade; discretion tested by a hundred secrets; tact tried in a thousand embarrassments; and, what are more important, Heracleian cheerfulness and courage. So it is that he brings air and cheer into the sickroom and often enough, though not as often as he wishes, brings healing.

RELATION OF PHYSICIAN TO PATIENT

It is well to give heed to what is meant by a learned profession as distinguished from a trade or business. The professional man is guided by the ideals of his profession, rules of conduct which have been handed down and which are embodied for the medical man in the Hippocratic Oath. He is primarily a learned man who depends on his knowledge as his stock in trade. He has specialized knowledge over and above that of the common man in relation to some particular topic. Perhaps the thing that distinguishes him more than anything else is the peculiarly personal relation to the client or patient which he enjoys, a confidential relationship, a situation in which he is adviser, guide and friend, a situation in which his interest does not cease when the particular transaction is concluded. He is an individualist, one who functions far more efficiently without regimentation or coercion, but rather requires the opportunity to utilize freely his own initiative and judgment within the limits of his professional code of ethics.

He has an interest in the results of this relationship in which he is called to advise, which is over and above the cash recompense which he receives; in fact, in the practice of medicine it is all too often the case that no monetary recompense is received at all, and more frequently the recompense is wholly inadequate to the value of the services rendered. The physician does not consider that he is receiving a *quid pro quo* when he is paid by his patient. He is entitled to a living, but more than that he takes a satisfaction in seeing that the results of his advice have brought aid and comfort to the person who sought it.

Another feature is the disregard of fixed hours, the readiness to be of service whenever called on. He does not count on regular hours. He realizes when he takes up the study of medicine that his sleep will often be interrupted,

that his time will not really be his own, and he rejoices to feel that he may be called on when others are in need regardless of his own comfort. One other point of distinction is the principle as laid down in the Hippocratic Oath that he will teach this art to others, if they wish to learn it, "without fee or stipulation." Such are some of the distinctions which set off the learned professions, and particularly the profession of medicine, from business.

WILLIAM ALANSON WHITE

We have been deeply touched this morning by the presentation of the oil portrait of Dr. William Alanson White, the gift of the faculty to the school. I look on Dr. White as the ideal medical man. He was a student; he always wished to learn. He was a teacher, always happy in imparting his knowledge to others, a gift which he had in rare measure. He was deeply interested in the patient and desired first to understand the nature of the disorder. Whether or not he brought healing, he always brought comfort. At the same time he remained a human being, a man in close touch with his fellow men, a man of wide and scholarly interests.

A CENTURY OF PROGRESS

The significant advances in medicine in the last century are too many to be enumerated here. Consider the advances of bacteriology, the significant work of Morton, Lister and Pasteur, and more recently of Banting and his development of insulin, the work of Theobald Smith and McKinley in bacteriology, the work of Folin in chemistry and of Cannon in physiology, the development of the knowledge of the vitamins and of the endocrine glands, and of surgery. Perhaps even more important is the aspect of preventive medicine for which Walter Reed did so much. Today diphtheria, typhoid and many other diseases are virtually unknown. New horizons are being discovered daily in the field of allergy.

Let us not be deceived into thinking that human improvement is nearly ended. There is ample room for improvement. Much more is to be learned concerning the possibilities in the field of heredity and constitution, and in bacteriology with particular reference to the virus diseases and the development of biologic tests. Chemotherapy is only beginning. Surgery is on the threshold of new developments. The newer anesthetics in the field of obstetrics have revolutionized the practice of that specialty within the past few years. There is one field, however, on which medicine has hardly yet begun—medicine is just discovering man! So much in the past has been devoted to the parts of man, to his various organs, systems and specific functions that too little has been thought about man himself, the social animal whose principal significance is his relations with other

men. Dr. William A. White probably did more than any other medical man in this country to emphasize the importance of the individual, the "organism-as-a-whole," as he called it, a something which is greater and more important than the sum of all its parts, and indeed something different from the sum of its parts. He emphasized the fact, now just beginning to be recognized generally, that the influences which impinge on one from the outside, as well as the conflicts which arise from one's unconscious, have much to do with the physical functioning of the organism. So much attention was focused on the gastrointestinal and circulatory tract that it was forgotten that they were parts of an individual who was perhaps expressing in this particular way and by these particular symptoms his emotional conflicts. The field of psychosomatic medicine is in its infancy. It is encouraging to note recently in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* moderately frequent references to the psychic factors in disease. A tremendous expansion in the psychiatric approach to medicine may be looked for, and in this field we shall be constantly indebted to the contributions of Dr. White.

Even though the world is troubled, we may look for peace and satisfaction in the field of medicine, which is only at the beginning of possibilities of service and benefit to mankind. That medicine will continue as a profession in the hands of men possessed of individual initiative and of professional ideals we need have no doubt.

MEDICAL RESEARCH: THE STORY OF SULFANILAMIDE

Abstract of address by Dr. E. K. Marshall Jr. published in the North Carolina Medical Journal, March 1940.

A school of medicine has primarily two objectives: the training of future physicians and the advancement of knowledge by medical research. For the attainment of the first, the second, properly pursued, is necessary. Organized medical research, at least in the so-called preclinical subjects, is a recent innovation. With the partial exception of the anatomic laboratory, laboratories in medical schools for the training of students and for research are largely creations of the last three quarters of a century. The first pathologic laboratory was founded by Virchow in Berlin in 1856; physiologic chemistry as a separate discipline split off from physiology quite late, and Hoppe-Seyler headed the first independent laboratory devoted to this subject at Strasbourg in 1872; pharmacology as the experimental science we now know began when Buchheim established its first laboratory in his private house at Dorpat in 1819. Coincident with the growth of organ-

ized laboratories for medical research the whole face of medicine has changed, and it is probably no exaggeration to say that a greater advance has been made in medicine in this seventy-five year period of laboratories than in all previous medical history. The lot of the diseased person today is immeasurably improved over what it was a hundred years ago. This improvement is the result of the labors of thousands of unknown medical research workers before whom stands the challenge of the prevention, alleviation and cure of human diseases. The lessons of science show, however, that the investigator having a definite practical goal in view frequently defeats his own ends by his impatience of any but the paths that seem direct and obvious. Important discoveries come generally from the work of those who seek knowledge for its own sake. The man into whose lap the fruit of discovery falls has builded on countless pieces of research and the long labors of a host of other investigators. No one can tell when knowledge acquired by an investigator satisfying his intellectual curiosity in a field of medical research apparently quite remote from practical things may be vital to the health of mankind.

Permit me to illustrate. You all know that in the last three years sulfanilamide has been used for the treatment of infections. Its introduction into medicine is to be ranked with the two great therapeutic discoveries of all medicine—the discovery of anesthesia and that of aseptic surgery. The story starts in 1904, when Ehrlich and Shiga first showed that a fatal experimental infection of mice caused by a trypanosome could be cured by a single injection of a relatively harmless red dye. Six years later Ehrlich announced the discovery of a cure for syphilis. Despite advances since Ehrlich's time in the chemotherapy of protozoan infections, nothing of practical importance was developed in the chemotherapy of bacterial infections until the sulfonamide group was introduced. In 1911 Morgenroth and Levy found that a chemical related to quinine—ethylhydrocupreine—would cure pneumococcic septicemia in mice. However, when this remedy was tried in pneumonia in man it was found too toxic to be given in sufficient dosage for effective therapy. In 1908 sulfanilamide was prepared by a chemist, Gelmo, working at the Royal Technical Hochschule of Vienna, apparently solely to satisfy his curiosity. A year later chemists at Elberfeld, Germany, prepared azo dyes with sulfonamide groups and found that they were distinguished by greater fastness to washing and milling than the corresponding sulfonamide-free products. No attempt was made at this time to apply these compounds to the control of bacterial infections. Domagk announced in 1935 that an azo dye containing the sulfonamide group prepared by Mietsch and Klarer would cure an

otherwise fatal streptococcic infection in mice. This compound, azosulfamide, was originally called prontosil. Clinical reports attesting the efficacy of azosulfamide in patients with streptococcic infections appeared shortly before and at the same time as Domagk's announcement of his discovery. Workers at the Pasteur Institute late in 1935 suggested that azosulfamide was broken down in the body to form sulfanilamide, which was found to be as effective as azosulfamide. This important observation demonstrated that a relatively simple organic compound was effective as a chemotherapeutic agent in streptococcic infections. English investigators in 1936 confirmed, as Long and Bliss did later in America, the fact that both azosulfamide and sulfanilamide would cure an otherwise fatal streptococcic infection in mice. With the publication of a paper in 1936 by Colebrook and Kenny of Queen Charlotte Square Hospital in London on the results in child-bed fever, much interest was awakened in these new drugs.

Sulfanilamide has been proved to be a specific in certain infectious diseases in human beings. It produces however at the same time in some cases toxic effects, some of which may endanger the patient's life. Numerous drugs allied to sulfanilamide have been tried. Sulfapyridine has proved about as effective in pneumococcic pneumonia and meningitis as is sulfanilamide in hemolytic streptococcus infections. The question of the mechanism of action of these new drugs is important. If it could be solved, the search for still better drugs for treating infections would be put on a firm scientific basis. Research is needed to complete the picture.

THE PREDICTIVE VALUE OF THE MEDICAL APTITUDE TEST

A study was made at Vanderbilt University School of Medicine, Nashville, Tenn., of 191 students who had taken the medical aptitude test and also of about fifty-five students who were accepted without having taken the aptitude test. The records of the students studied covered in all a period of nine years. The object was to compare the merits of the aptitude test and the premedical grades in predicting the degree of success of medical students; also to determine the degree of correlation between aptitude test scores of premedical students and their success in the four years of medical school work. The data are presented in charts published by Beverly Douglas,¹ the assistant dean. Obviously, if the aptitude test can help to predict the success of a student in the freshman year it is valuable. The aptitude test has never been required at Vanderbilt; nevertheless it has always been advised and in some cases insisted

1. Douglas, Beverly: A Study of the Predictive Value of the Medical Aptitude Test at Vanderbilt School of Medicine, J. A. Am. M. Coll. 13: 380 (Nov.) 1938.

on. It should not be regarded, however, as the sole criterion by which a student should be judged. In summarizing the data presented, the author says that the predicted value of pre-medical grades, both scientific and general, is fair in the case of certain classes and poor in certain others. In none was it significant enough to be used as a sole and presumptive index of a student's likelihood to succeed in medical school. These studies show that premedical grades were not as good a criterion as the aptitude test in predicting the success of students at Vanderbilt; nevertheless they were considered valuable and are expected to become more so as certain colleges improve their courses and grading systems. When the personal rating forms, the premedical grades and the aptitude test scores are considered together

they give a more accurate prediction of a student's worth than when any one or any two criteria are considered in choosing between so many applicants when there are so few places available (each year at Vanderbilt there are more than 700 applicants for the fifty available places), every criterion which has any value should be taken into account. Certain students will nevertheless later defeat all predictions. The author cites a case. Dr. William Sydney Thayer was expelled from Harvard because of a boyish prank and probably would not have been allowed to enter medical school had it not been for the sympathetic efforts of an old English clergyman. The author hopes that, in the endeavor to choose the right applicants for medical training, no Parés and no Oslers will be excluded.

Comments

The number of crippled children registered in forty-five of the states of this country at the beginning of 1940 was 188,579, of which 29,849 were registered in New York, 26,953 in Illinois, 15,343 in North Carolina, 11,304 in Michigan, 10,174 in Texas and 10,049 in New Jersey. Poliomyelitis caused crippling in 36,271 of these persons under 21 years of age, cerebral palsy in 19,172, paralysis due to birth injury exclusive of cerebral palsy in 4,532, tuberculosis of bones and joints in 7,196, osteomyelitis in 11,112 and burns in 4,161.

Hugo Iltis, the biographer of Gregor Mendel, is now professor of physiology at Mary Washington College, Fredericksburg, Va. Dr. Iltis was born in Mendel's home town, Brno, Czechoslovakia, and besides writing the only biography of Mendel he built up the only Mendel museum in the world. A distinguished committee with Henry A. Wallace, Secretary of Agriculture, honorary chairman, has become interested in establishing a Mendel museum in the United

States. Consideration is being given to an appeal to the public for subscriptions to make the Mendel exhibit available to the public. Dr. Iltis collected from the Augustinian monastery at Brno, where Mendel did his work, the original manuscripts of Mendel's papers on atomic heredity, Mendel's diary, letters to and from his contemporaries and Mendel's notes on genetics, bees, meteorology and horticulture.

The number of applicants for admission to the freshman class of seventy-seven medical colleges in the United States in 1939 was 11,800, of whom 6,211, or 52.7 per cent, were accepted and 5,589 were rejected. The 11,800 applicants made 34,871 applications, one applicant having made as many as forty applications, none of which were accepted. The number of applicants dropped in 1939 below 12,000 for the first time in eight years. The percentage of applicants accepted has dropped from 62.1 in 1933 to 52.7 in 1939.—*Fred C. Zapffe*, Chicago, Secretary, Association of American Medical Colleges.

DO YOU KNOW WHAT PHYSICIAN—

1. Sent Paul Revere on his famous ride to Concord and Lexington and later was killed at the Battle of Bunker Hill?

2. Invented (1861) the revolving machine gun, which bears his name?

3. Was Premier of France during the first World War?

4. Wrote "In Flanders' Fields"?

5. Was the first to evolve a system of shorthand writing?

6. Wrote the Adventures of Sherlock Holmes?

7. Was the first president of the Chinese Republic?

The answers are on page 1150.

Medical College News

Medical schools, hospitals and individuals will confer a favor by sending to these headquarters original contributions, reviews and news items for consideration for publication in the Student Section.

The Gold-Headed Cane

Leslie L. Bennett, '40, University of California Medical School, San Francisco, was awarded the gold-headed cane which is given each year to the student adjudged most likely to become eminently successful in his profession. Archer Jule Sokol, '41, and David E. Price, '40, received honorable mention in the cane competition and were awarded copies of a book describing the ancient cane ceremony. The university ceremony is adapted from an old English tradition in which a single gold-headed cane was handed down through several generations of eminent British physicians.

First Appointee to the Luckhardt Fellowship

At the annual banquet of alumni of Rush Medical College in Chicago, June 6, Prof. Anton J. Carlson, toastmaster, announced that contributions to the Arno B. Luckhardt fellowship were now sufficient to provide an income of about \$1,000 a year. The first appointee to the scholarship is Dr. Alexander Rush, the great-great-grandson of Dr. Benjamin Rush, signer of the Declaration of Independence, in whose honor Rush Medical College was named.

Commencement at Jefferson

The graduating class of 125 members at Jefferson Medical College of Philadelphia at the 115th commencement, June 7, brought the total number of graduates of this school to 16,694. Thirty-one members of the graduating class were commissioned first lieutenants in the medical section of the Officers' Reserve Corps, the commissions being presented by Lieut. Col. John F. Corby, M. C., U. S. Army. The graduates originated in twenty different states, Hawaii and Puerto Rico. The class presented to the college a portrait of the dean, Dr. Henry K. Mohler. The valedictory address was delivered by William L. Phelps, Ph.D., Yale University, New Haven, Conn., whose subject was "The Art of Living."

Harvard's National Scholarships

The recipients of national scholarships for admission this fall to Harvard Medical School, Boston, were announced June 9. They are James S. Clarke, LaGrange, Ill., awarded the Daniel Fiske Jones National Scholarship; Martin E. Flipse, Douglaston, L. I., N. Y., the Edward S. Harkness National Scholarship, and Windsor C. Schmidt, Rye, N. Y., the Harvard Medical School National Scholarship. This is the fourth year of Harvard Medical School's scholarship plan.

Additional medical school scholarships totaling \$1,300 were awarded to James P. Dixon Jr., Yellow Springs, Ohio (Matthew and Mary E. Bartlett Scholarship); Lytt I. Gardner, Reidsville, N. C. (Abraham A. Watson Scholarship), and Frank E. Trobaugh Jr., West Frankfort, Ill. (Isaac Sweetzer Scholarship).

Louisiana's Graduating Class

Sixty-nine students of Louisiana State University School of Medicine, New Orleans, received the M.D. degree at the commencement in Baton Rouge, June 3, and forty-five of them were from the state of Louisiana. The five students who made the highest averages were, in order of standing, James T. Nix Jr., New Orleans; Harold B. Levy, Shreveport; William Rigsby Hargrove III, Oakdale; Milton Flocks, Baltimore, and Marion J. LeDoux, New Orleans.

Colorado Students Organize Seminars

The junior students at the University of Colorado School of Medicine, Denver, recently organized seminars in surgery, medicine, obstetrics and psychiatry which will meet monthly at the home of a sponsoring faculty member. The groups are limited to fifteen students, two or more of whom read papers at each meeting. The seminar in medicine, sponsored by Dr. John G. Ryan, is devoting its first two meetings this year to kidney diseases; the seminar in surgery, sponsored by Drs. Frederick Harper, Casper Hegner and Leonard Freeman Jr., is to devote this year's seminars to surgery of the gastrointestinal tract. The seminar in psychiatry, sponsored by Dr. Edward Billings, will devote all of this year's meetings to psychosomatic problems, especially those referable to the heart and gastrointestinal tract. The organization of the seminar in obstetrics has not been entirely completed.

California's Osler Society

Twelve members of the sophomore class of the University of California Medical School, San Francisco, met recently to form an Osler society. The organization will follow the tradition of the Osler Society at McGill University Faculty of Medicine, Quebec, which society has served as a model for many similar societies in this country and abroad. The California society will meet four times a year, at which time papers will be read by members on subjects related to medical history and to the life of Sir William Osler.

Award to Oklahoma Student

The University of Oklahoma has announced three \$50 scholarships to be awarded annually to a member of the senior class of the schools of medicine, law and engineering whose grades are in the upper 25 per cent of the class, who has earned by personal service at least 50 per cent of the cost of his college education to date and who has developed a sense of self reliance and honesty of purpose. Mr. James Lowden Dennis, '40, was this year's recipient from the school of medicine.

Western Reserve Increases Tuition Fees

Western Reserve University announces that the basic fee in its medical school will be increased from \$400 to \$500 for all classes beginning with the academic year of 1941 to 1942. The announcement is made a full year in advance to give students the opportunity to adjust themselves to the situation. The increase is necessary to meet in part the diminished returns of endowments. Incidental fees remain essentially at the present level.

Louisiana Discontinues the Tiger

The *Tiger*, which has been the weekly official organ of the students of the Louisiana State University School of Medicine, New Orleans, since 1932, has been discontinued and a monthly publication to be known as the *Journal of the School of Medicine of Louisiana State University* will be substituted for it. The editor of the new publication is Thomas R. Wilson, '41; Laurence B. Weiss, former managing editor of the *Tiger*, will serve as co-editor. Drs. Edward L. Burns, Hugh C. Ilgenfritz and George W. McCoy will serve as an advisory board from the faculty.

Premedical Symposium at Duke

Duke University School of Medicine, Durham, N. C., presented a symposium on premedical education, April 26, under the auspices of the premedical society of the university. Dr. Frederic M. Hanes was chairman of a clinic for premedical students held in the amphitheater of Duke Hospital, at which several members of the faculty made brief remarks. The clinic was followed by an inspection of the hospital and of the medical school by the premedical students, and at 4 p. m. the public also was invited to hear an address on "Educational Backgrounds for the Study of Medicine" by the dean of the University of North Carolina School of Medicine, Dr. William deB. MacNider. In the evening the public was also invited to a round table discussion on premedical education, at which Dr. Wilburt C. Davison, the dean of Duke University School of Medicine, was chairman. Question boxes were placed at the various meetings and any one present could thus bring up a topic for the round table discussion. The participants in the round table discussion included Dr. MacNider, Dr. Thomas T. Jones, Dr. Charles E. Gardner, several members of the premedical faculty, William M. Eagles, president of the premedical society, and Frank Bone and Arthur A. Morris Jr., premedical students, graduates of the university in 1940. The president of the premedical society was chairman of one of the afternoon meetings.

Wayne Withdraws from Association of Students

The Wayne University College of Medicine chapter of the Association of Medical Students announced, June 5, the severance of its affiliation with that association. This was felt necessary owing to extramedical activities of the Association of Medical Students which the Wayne chapter felt inconsistent with its own policies and those of the Wayne University College of Medicine, Detroit.

Prize Papers at Indiana

Three courses given at the Indiana University School of Medicine, Indianapolis, require term papers: bacteriology, surgical pathology and history of medicine. Recently, however, the heads of all departments were asked for outstanding case reports, essays submitted by students or statistical studies, and 325 papers were received, of which the following were selected for prizes:

JUNIORS

Miss Antha A. Hamilton, First prize—"The Treatment of Hemophilia".....	\$20.00
Harry D. Schell—"Capillary Permeability".....	15.00
Julius T. Steffen—"Physiology of Lymph Production and Flow".....	15.00
Joseph R. Eastman Jr.—"Arteriovenous Aneurysms".....	15.00
Richard K. Parrish—"Local Tissue Immunity".....	15.00
Philip W. Hedrick—"Air Borne Infections in the Surgery".....	15.00
Ottis N. Olvey—"Effects of Obstetrical Anesthetics and Analgesias on the Newborn".....	15.00

SOPHOMORES

Thomas L. Dittmer—"Typhoid Carriers".....	\$15.00
Guy B. Ingwell—"Rocky Mountain Spotted Fever with Special Reference to Indiana".....	15.00
Everett L. Kalb—"Use of Heparin and Sulfapyridine in the Treatment of Subacute Bacterial Endocarditis".....	15.00
Helen M. Sisson—"Impetigo Contagiosa Neonatorum".....	15.00
Otis R. Bowen—"The History of the Practice of Obstetrics".....	15.00
Edgar A. Thompson—"Blood Transfusion".....	15.00

Alpha Omega Alpha

The following members of the class of 1940 at Washington University School of Medicine, St. Louis, were elected to the Alpha chapter in Missouri of Alpha Omega Alpha: Russell J. Crider, Robert E. Buck, Perry C. Gillette, Horace M. Wiley, Seymour Brown, Richard L. Landau, Mary C. McFayden, Paul Guggenheim, Benjamin Strehlman, Wallace Rindskopf Jr.,

Llewellyn Sale Jr. and Leabert R. Fernandez. The following members of the class of 1941 were also elected at this meeting: Henry S. Guterman, Leon Kahn and Earl W. Sutherland Jr.

Temple University

The freshman class at Temple University School of Medicine, Philadelphia, gave its annual dance February 9 in Mitten Hall in honor of the sophomore class. The special guests on this occasion were the junior and senior classes, Dr. and Mrs. Earl A. Schrader, Dr. and Mrs. Robert H. Hamilton Jr. and Dr. Philena Chase. The favors were mother-of-pearl lavalieres with the medical school insignia superimposed.—Dr. Virgil H. Moon, professor of pathology at Jefferson Medical College of Philadelphia, addressed the sophomore class recently on "Shock: Its Mechanism and Pathology." The entire student body was addressed by Dr. Gilbert Dalldorf, chief of laboratories at Grasslands Hospital, Valhalla, N. Y., on "The Clinical and Pathological Evaluation of the Vitamins."—The Babcock Surgical Society has elected John B. Roxby Jr. '41 as secretary-treasurer; next year Mr. Roxby will succeed to the presidency. Student papers were read before the society January 11 by George Shugert '40 on "Primary Tumors of the Lung" and by Joseph Reno '41 on "Cryptorchism"; J. Guy Butters '41 and Joseph R. Connelly '40 read papers before the society, February 14, on "Treatment of Varicose Veins" and "Intercostal Neuralgia," respectively.—The basketball team at Temple University School of Medicine—Jack Moore, Robert Deen, Frederick Reese, Chauncey McGeorge, Norman MacKenzie, Sidney Sedwick, Taras Rybachok, Murray Sigman and Frank Viggiano—has won its fourteenth consecutive game, the recent victims having been Glassboro State Teachers College Alumni, the Temple University football team, and Temple University hospital interns.

Expenses at Long Island in 1940

The secretary for student employment at Long Island College of Medicine, Brooklyn, Dr. Milton B. Handelsman, sent questionnaires to all students at the college regarding their expenses, sources of income and financial difficulties, and 86 per cent of them were returned answered. From these data, the average estimated budget for the present school year for students living at home is from \$1,035 to \$1,135; for those boarding near the school the estimate is from \$1,390 to \$1,490. If scholarships were available to cover the cost of tuition, a student living at home would require only an additional \$425, and a student boarding near school \$780. Among the expenses listed in the average budget were tuition \$610, books and instruments \$100, clothing and the like \$100, room \$180, food \$250, travel expenses \$150, recreation from \$50 to \$100, incidentals from \$25 to \$50, and medical and dental fees from \$10 to \$25.

The data showed that the chief sources of income of 50 per cent of the students were from their parents; however, 14.8 per cent of the seniors, 8 per cent of the juniors, 10.5 per cent of the sophomores and 3.5 per cent of the freshmen were entirely independent of parental assistance. Of the seniors receiving parental support, 58.5 per cent felt that their studies imposed a severe strain on the family finances; of the juniors, 54 per cent; of the sophomores, 37.7 per cent, and of the freshmen, 26.4 per cent. There were many other sources of income; 16.7 per cent of the seniors worked during the school year, about 26 per cent of both the juniors and the sophomores, and 10.3 per cent of the freshmen. Twenty-four per cent of the seniors were

relying on repayable loans, about 12 per cent of the juniors, 15 per cent of the sophomores and 12.7 per cent of the freshmen. Personal savings accounted for the incomes of 16.7 per cent of the seniors and of 21, 15.1, 8.1 of the other classes, respectively. One and nine-tenths per cent of the seniors relied on their spouses for their income, 1.3 per cent of the juniors and 1.2 per cent each of the sophomores and freshmen. The usual amount earned by students performing small jobs through the school year varied from \$150 to \$200. The students who worked during the summer earned on the average a maximum of \$250. With the exception of the freshmen, more than 50 per cent of the students expressed a desire to obtain some remunerative work. Such positions as policemen, chauffeurs, hotel clerks, lifeguards, laboratory assistants, playground directors, counselors in camps, illustrators and seamen were filled by the students who were employed.

Harvard Students in Peru

Henry F. Allen, William P. Carter, Calvin H. Plinpton, Calderon Howe and Ben Eiseman, all of the class of 1943 of Harvard Medical School, Boston, have just returned from Lima, Peru, where, under the direction of the Institute of Public Health, they completed during the summer a survey of the diseases of the rural population, the most prevalent of which were said to be leishmaniasis, oroya fever and verruca peruana.

Prizes Awarded at Colorado

The following prizes were recently awarded to students at the University of Colorado School of Medicine, Denver: Miss Dorothy J. Clark, '42, received the 1940 Chester H. Elliott Memorial Prize in pathology, amounting to about \$30, for showing the greatest proficiency in the second year courses in pathology. Robert S. Redwine, '43, received the 1940 Alpha Omega Alpha Prize of \$25 in anatomy, the winner having been designated by the faculty of that department. Miss Winifred M. Riggs, '41, was awarded the Carbon Gillaspie Memorial Prize of \$25 in applied anatomy for having shown exceptional scholarship and technical skill in the course in that department. Robert W. Rasor, '41, and Chester P. Stevenson, '41, received the 1940 \$10 prize offered by Dr. John G. Ryan for the best case report prepared by a senior or junior student.

Pennsylvania State Board Questions

The following questions were given by the Pennsylvania State Board of Medical Education and Licensure at the examination in Harrisburg, July 10, 1940:

GYNECOLOGY AND OBSTETRICS

1. Outline the management of the second stage of labor.
2. Discuss the treatment of pregnancy when complicated by essential hypertension and appearing in the first trimester.
3. Given a symmetrical pelvis with a diagonal conjugate diameter of 10.5 cm., how would you determine the proper management when the patient is at term?
4. Differentiate "retained placenta" from "adherent placenta"; outline treatment in a case of retained placenta.
5. Give the clinical course of a case of pernicious vomiting of pregnancy. What are the salient points in its treatment?
6. How will you diagnose and treat a case of infected incomplete abortion?
7. In a woman 30 years of age, what symptoms would occur from a retrocessed uterus, and how would you diagnose this condition? Detail one method of treatment.
8. What are the most frequent causes of postmenopausal uterine bleeding? Select one and give its diagnosis and treatment.
9. Give the differentiated diagnosis of four conditions which may cause enlargement of the abdomen in a woman 40 years of age.
10. What are the clinical aspects of trichomonas infestation of the vagina? Differentiate this from other types of vaginitis.

Prizes Awarded at Western Reserve

Gerald T. Kent, '40, a graduate of Western Reserve University School of Medicine, Cleveland, has been selected by the faculty of the school for the Charles F. Hoover Scholarship for 1940 in recognition of his outstanding scholastic record. Dr. Kent will serve as assistant in pathology until February, when he will take up his duties as intern in medicine at the University Hospitals.—The annual Alpha Omega Alpha awards have been made as follows: first prize to Robert E. Eckardt, '43, for his paper on "Vitamin B₁₂, Its Isolation, Synthesis and Physiology"; second prize to Daniel A. Brody, '40, for his paper on "Physical Factors in Gastric Evacuation"; third prize to John M. Cook, '40, for his paper on "A Study of Carbohydrate Digestion."—Samuel R. Ziegler, '40, was awarded the senior prize in obstetrics, the gift of Dr. Edwin C. Garvin; Jac Sidney Geller, '40, was awarded the senior prize in surgery, the gift of Dr. Elliott C. Cutler, and Eugene R. K. Leiter, '43, was awarded the Herbert S. Steuer Memorial Award for special work in anatomy.

Dr. Alvarez Gives McCoy Lecture

The students in New Orleans medical schools and the interns at Charity Hospital were invited to the inaugural lecture of the George W. McCoy lectureship, given at the Jung Hotel, March 26, by Dr. Walter C. Alvarez, of the Mayo Clinic, Rochester, Minn., on "The Origins of Modern Medicine." This annual lecture has been established by the Phi Beta Pi fraternity in honor of Dr. George W. McCoy, for many years a prominent officer in the U. S. Public Health Service and recently also professor of preventive medicine and public health at Louisiana State University School of Medicine. Dr. McCoy is a member of the Council on Pharmacy and Chemistry of the American Medical Association, of the National Board of Medical Examiners, of the Permanent Standards Commission of the Health Section of the League of Nations and of many scientific societies. He was awarded the Sedgwick Medal of the American Public Health Association in 1921.

Vanderbilt Sophomores Elected to Honorary Society

The Vanderbilt sophomore medical students elected to the local chapter of Alpha Omicron Alpha, national honorary medical fraternity, this year were John R. Hilsenbeck, Charles L. Cogbill Jr. and James H. Baxter. Only three members of the sophomore class are taken into this honorary fraternity each year, membership in which is based on scholarship and character.

Maryland's Recreation Center

The completion of the spacious Frank C. Bressler Research Laboratory has provided two floors in the Gray Laboratory Building which have been given over to the students for a lounge and recreation center. The students have enjoyed a program of medical motion pictures, lectures and the first student body dance in many years.

Undergraduate Honor Society at Louisiana

Announcement has been made of the formation of The Circle, an undergraduate honor society in the Louisiana State University School of Medicine, New Orleans, under the sponsorship of a faculty committee consisting of Drs. B. I. Burns, dean, Charles Midlo and James D. Rives. The fourth year membership is limited to the upper tenth of the senior class, and the third year membership to the three highest ranking students in the junior class.

Iowa Student-Faculty "Mixers"

Two committees have been appointed independently at the State University of Iowa College of Medicine to bring the students and faculty members together in activities of a social and cultural nature. The Student Council comprises one of these committees and the chairman of the other is Helen L. Dawson, Ph.D. Last year the two committees carried out similar programs providing for special speakers, movies and music, followed by a longer interval of good fellowship, with refreshments. The highlights of these programs were "Colored Movies of Old Mexico," made by Dr. Nathaniel G. Alcock; a talk by Dr. William D. Paul on "American Pattern Glass," a hobby; "Tall Tales of the Mississippi," by William J. Petersen, Ph.D., of the history department, and an amusing and scientific discussion of "Foulk's Law as a Basis for Predicting Postcurricular Achievement," by Col. J. J. Hinman. One of the most popular programs was a "Professor Quizz," in which a team of students and a team of faculty members opposed each other and for which the student prize was won by John M. Rhodes and the faculty prize by Walter R. Ingram, Ph.D.

Syracuse Personals

Edward M. Nutting, '41, of Syracuse University College of Medicine, Syracuse, N. Y., lost his life this summer by drowning.—Miss Mary Elisabeth Herberich, a senior, has been awarded the Dr. Menzo W. Herriman Scholarship, a full tuition award which is given annually to one of the five highest ranking students in the senior class. Miss Herberich is the first woman student to receive this award.—Six of the forty-eight new freshmen medical students at Syracuse this fall are sons of physicians. The class also includes three women.

Dance to Aid Students

The annual dance of the students of Long Island College of Medicine, Brooklyn, cleared about \$400, which was turned over to the Student Loan Fund.

Tufts Freshmen Awarded Commonwealth Scholarships

The Commonwealth Fund has awarded scholarships to four students who will enter Tufts College Medical School, Boston, this fall as freshmen. Each of the four recipients will receive \$1,000 for each of his four years of medical training, but he must agree to practice in a rural community in his home state at least three years following his internship. The scholarships have been awarded to C. Clark Streeter, West Somerville, Mass.; Clarence W. Whittaker, Easton, Maine; Frank E. Perron Jr., Manchester, N. H., and Theodore W. Ling, St. Johnsbury, Vt. All four recipients have B.S. degrees.

Prizes Awarded to Tulane Students

The dean of Tulane University of Louisiana School of Medicine, New Orleans, Dr. Maxwell E. Lapham, announced the following list of prizes and honors awarded to some of the 1940 graduates: William H. Harris Jr., a gold medal for the highest combination average in the four year course in medicine. This is the Isadore Dyer Memorial Medical Scholarship Prize. Stephen L. Stigler, the Sidney K. Simon Prize of \$50 for his essay entitled "Vitamin K." A similar prize was awarded to Charles J. Edwards Jr. for his thesis "Alcoholism and Vitamin Deficiency." Mayo L. Emory and John J. Christian were awarded copies of Musser's book on internal medicine for the best theses in medicine. Edward B. Ferguson Jr., of the freshman class, was awarded the biochemical scholarship cup in the annual competitive oral examination.

Colorado Juniors Give Psychiatric Plays

The junior class at the University of Colorado School of Medicine, Denver, gives an amateur play each year dramatizing some psychiatric problem or situation. The plays are produced, acted and directed by members of the class, and the costs are underwritten by Dr. Franklin Ebaugh, professor of psychiatry. The last production, entitled "Doctor, Feel My Pulse," dealt with a family situation in which a mother-in-law and a timid husband make a young wife's life miserable. The family physician recommends calling in a psychiatrist, who endeavors to resolve the family problems by showing the wife how to use her wits, the husband, how to become more masculine and the mother-in-law how to be less domineering. The play was directed by John Ames, '41, and the parts in the order of mention here were taken by Winifred M. Riggs, '41, Claude O. Roberts, '41, Mary Barker, a student nurse, Howard Hamlin, '41, and John Benwell, '41.

Ohio Personal

Howard J. Scott, a senior at Ohio State University College of Medicine, Columbus, is the recipient of the first award from the Conly-Coleman Scholarship Fund, which provides for a full year's tuition. Our correspondent writes: "Because of 'Scotty's' sincere and indomitable spirit, his selection will be greeted by the hearty approval of his classmates."

Awards to Jefferson Students

At the 115th commencement of Jefferson Medical College of Philadelphia, June 7, the following students were awarded prizes:

Alan M. Schaeffer received the Henry M. Phillips Prize of \$75, awarded on recommendation of the professor of medicine to the graduate in his opinion the most worthy.

Harvey K. Mechanik, the Henry M. Phillips Prize of \$75, awarded on recommendation of the professors of surgery to the graduate in their opinion most worthy.

William W. Kitchin, a gold medal, awarded by bequest of Dr. Francis W. Shain for the best essay on a subject pertaining to the practice of medicine.

James R. Herron Jr., a gold medal, awarded by bequest of Dr. Francis W. Shain for the best essay on a subject pertaining to surgery.

Theophilus H. Boysen III, \$25 by Professor Brooke M. Anspach for the best examination and clinical report on gynecology.

Richard H. Saunders, \$25, by Prof. Horace J. Williams for the best examination in otology.

George F. Lull Jr., a gold medal, for general excellence in clinical surgery, in memory of Francis T. Stewart.

Clyde A. Collins, \$25, by Prof. Norris W. Vaux for the best examination in obstetrics.

Francis X. Bauer, \$25, by Prof. Edward L. Bauer for the best examination in pediatrics.

Harvey K. Mechanik, \$25, by Prof. Charles E. G. Shannon for the best examination in ophthalmology.

Thomas H. Auginbaugh Jr., \$25, by Prof. Louis H. Clerf for general excellence in laryngology and bronchoscopy.

John L. Simon, \$25, by Prof. Bernard J. Alpers for the best examination in neurology.

John C. Grier Jr., \$25, by Clinical Prof. Baldwin L. Keyes for the best examination in psychiatry.

Richard L. Wagner, a gold medal, for the best examination in therapeutics.

Alan M. Schaeffer, the William Potter Memorial Prize awarded to a graduate attaining the highest general average in the final two years of the medical course.

Harvey K. Mechanik, a medal, awarded by the alumni association for the best general average gained in the examinations for the entire curriculum.

Thomas M. Scariaciotoli, a gold medal, awarded by bequest of Dr. Francis W. Shain, open to undergraduates of the second year for the best essay or examination on a subject pertaining to physiology.

John A. Pilster, a gold medal, awarded on completion of the sophomore year to the student with the highest grade in anatomic subjects of the first two years.

Frank T. O'Brien, a gold medal, awarded by Prof. J. Parsons Schaeffer for the best thesis in the science of anatomy.

John L. Simon, the W. B. Saunders Company Prize for the best general examination at the end of the senior year.

Frederick B. Wagner Jr., the D. Appleton-Century Company Prize for the best general examination at the end of the junior year.

Tulane's Quiz in Biochemistry

Edward B. Ferguson Jr., '43, Tulane University of Louisiana School of Medicine, New Orleans, who was named winner of the annual biochemistry oral quiz, will be presented with a book and a loving cup to be held for one year. The ten students having the highest average in the biochemistry class are eligible for the quiz, which questions are asked by the entire biochemistry staff. William D. Davis Jr., '43, was named runner-up.

Iowa Personals

The annual Baldrige-Beye Memorial Prize of \$100 for original scientific work at the State University of Iowa College of Medicine was awarded to Albert P. McKee, '41.—Byron H. Evans and Dwight Sattler were awarded associate membership in Sigma Xi on the basis of scholastic excellence and original research.—The following medical students were elected to membership in Alpha Omega Alpha during the last year: Forest H. Coulson, Byron H. Evans, Robert H. Foss, John H. Laubscher, Frederic G. Loomis, John J. Maloney Jr., Robert C. Miller, James W. Standeven, Thomas F. Thornton Jr., George I. Tice, Charles A. Waterbury Jr., John M. Rhodes, Margaret L. Vanderwilt, Samuel V. Thompson and Henry E. Hamilton.

Senior Awards at California

In the award of the annual Guy K. Woodward competition for fourth year medical students at the University of California, San Francisco, the first prize of \$150 went to Julian S. Davis of San Francisco for his paper on "Coronary Occlusion with Special Reference to the Electrocardiographic Changes"; the second prize to Theodore E. Diller, San Francisco, for his paper on pellagra, and the third prize to Robert W. Godwin, Long Beach, Calif., for his paper on Ménière's disease. Milton Gordon, San Francisco, and Harry Levitt, Los Angeles, were given honorable mention. The awards were presented by Dr. William J. Kerr, professor of medicine.

Guest Lectures at St. Louis

Dr. Paul S. Barker, assistant professor of internal medicine, University of Michigan School of Medicine, Ann Arbor, addressed the junior and senior classes of St. Louis University School of Medicine at a special lecture on "Heart Disease in Pregnancy."—Dr. Robert S. Berghoff, professor of clinical medicine, Loyola University School of Medicine, Chicago, lectured at a seminar, April 24, on "Senile Ectasy." The lecture was sponsored by Alpha Omega Alpha.

Emory A. O. A. Members

At a dinner meeting in May, Emory University chapter of Alpha Omega Alpha honorary medical society at Atlanta, Ga., initiated the following new student members: Julian C. Pate, Tampa, Fla., John Ranson Lewis Jr., Louisville, Ga., and George L. Beale, Cairo, Ga. Following the dinner, the annual Alpha Omega Alpha lecture was presented by Dr. Virgil P. Sydenstricker, professor of medicine at the University of Georgia School of Medicine.

Virginia Personal

Dr. Reginald Fitz, Harvard Medical School, Boston, was the speaker at the commencement closing the one hundred and second session of the Medical College of Virginia, Richmond, June 4. There were sixty-eight candidates for graduation in medicine.

Premedical Club at Ohio State

Ohio State University's premedical club was formally installed, May 31, as a chapter of Alpha Epsilon Delta, national premedical fraternity, at which twenty-nine students and four faculty members were inducted as charter members. Honorary members of the charter group are Dr. H. E. Setterfield, associate professor of anatomy, and Dr. Raymond J. Seymour, professor of physiology at the college of medicine. The installation dinner was held in the Pomerene Hotel, with Emmett B. Carmichael, Ph.D., national councilor of the fraternity and a faculty member at the University of Alabama, as the installing officer. Following the dinner, the fraternity sponsored an open meeting. Membership is limited to juniors or seniors who have a cumulative average of B in all studies. Alpha Epsilon Delta which was founded at the University of Alabama in 1926 now has twenty-nine chapters. It was first limited to men, but since 1929 has been open to women also.

The Bel Award at Louisiana

Dr. James T. Nix Jr., '40, Louisiana State University School of Medicine, New Orleans, received the George S. Bel Memorial Award of \$50, which was given for the first time this year. The winner was selected by a committee of the faculty from the ten highest ranking students. Mrs. Bel stipulated that the award should be presented to the senior student who "symbolizes the highest ideals of medicine"; the prize was established in memory of her husband, the late Dr. George S. Bel, who was director of the department of medicine for many years.

Howard College

Dr. Louise H. Branscomb, Birmingham, Ala., addressed the twelfth annual founders' day banquet of the Howard College chapter of the Alpha Epsilon Delta honorary premedical fraternity, May 15, on "Women in Medicine."

"DO YOU KNOW WHAT PHYSICIAN"

Following are answers to the questions appearing on page 1145:

1. Dr. Joseph Warren of Boston, an ardent patriot. Dr. Warren had a high reputation as a physician and was retained by John Adams, who was later president of the United States, as his family physician.
2. Dr. Richard J. Gatling, who graduated from Ohio Medical College in 1850, after having become interested in the study of medicine through an attack of smallpox. He was born in North Carolina and was for some time a practitioner of medicine in Indianapolis. Dr. Gatling died in New York, Feb. 26, 1903, after the Gatling gun had been adopted by almost every great nation in the world.
3. Dr. Georges Clemenceau, who practiced medicine in New York and later in Paris as a dermatologist.
4. Dr. John McCrae of Montreal, Canada, who was lecturer in pathology and internal medicine at McGill University and formerly professor of general and special pathology at the University of Vermont, Burlington. Dr. McCrae was killed in service during the first World War.
5. Dr. Timothy Bright, who graduated in medicine at Cambridge, England, in 1574. His system had an alphabetical basis using the initial of each word.
6. Arthur Conan Doyle, who received his M.D. degree from Edinburgh in 1885. He was knighted in 1902.
7. Sun Yat-sen, who graduated from the College of Medicine in Hong Kong in 1892.

SIGNIFICANCE OF THE TONSILS IN THE DEVELOPMENT OF THE CHILD

CHAIRMAN'S ADDRESS

ALBERT D. KAISER, M.D.

ROCHESTER, N. Y.

During the last thirty years many significant facts have been ascertained relative to the growth and to the development of the child. Particular attention has been given to the status of the tonsils and adenoids as one of the factors that may influence the child's physical progress. In this period an increasing number of children have been classified as possessing hypertrophied or diseased tonsils resulting in the surgical treatment of the tonsils in nearly 50 per cent of urban children in the United States and England. This situation invites a survey of the tonsil problem and an evaluation of the tonsils as a factor in the child's development.

It is of interest to note that in 1888 W. Franklin Chappell⁵ surveyed 2,000 children in New York to determine the frequency of certain abnormal conditions of the tonsils. He concluded that 3 per cent of the children had tonsils sufficiently enlarged to require surgical treatment. Twenty years later Gibb⁶ reported on a group of boys at Girard College in Philadelphia and stated that 30 per cent were found to have either hypertrophied tonsils or adenoids or both. During the last twenty years more than 50 per cent of the children in many cities of the United States have been designated as having either hypertrophied or diseased tonsils which necessitated their removal. It is obvious, therefore, that either the lymphoid tissue of the child's nasopharynx has assumed a more formidable position in the throat or the standards for judging the significance of the tonsils have changed. It seems quite unlikely that the tonsils are more frequently hypertrophied today than they were forty years ago. With the lessened morbidity from such diseases as diphtheria and scarlet fever, considered potent factors in producing hypertrophy of the tonsils, one would expect to find fewer children with hypertrophied tonsils. This intensified interest in the tonsils, and the subsequent surgical treatment must be explained by the changed attitude toward the tonsils. In fact the real issue in the discussion dealing with the tonsil problem is to decide whether the widespread incrimination of the tonsils is scientifically sound and if it is in the interest of the child's health. Whatever

influences may have been responsible for bringing about the present attitude toward the tonsils and adenoids, it must be recognized that surgery of the tonsils has been widely accepted as both a therapeutic and a prophylactic procedure. The beneficial results following tonsillectomy in selected cases cannot be refuted. When, however, this procedure is applied to half of the children during their school years, it is reasonable to question whether the tonsils can be incriminated in such a high percentage of children and whether the surgical treatment of the tonsils in these children contributes anything to their health.

THE TONSIL PROBLEM TODAY

The problem that confronts the physician today is When should the tonsils be considered a menace to a child's development? There is no dispute as to the surgical procedure when once this decision is made. In obvious cases of hypertrophy and infection of the tonsils the clinical signs are sufficient to direct the course the physician must take. However, in many of the children subjected to surgical treatment of the tonsils in recent years the clinical evidence for tonsillectomy was not clear, for it was not certain that the suspected tonsils were influencing the child's health favorably or unfavorably. For years physiologists have assigned various functions to the tonsils which have not been uniformly accepted. Bacteriologists have reported on the bacterial flora found in the tonsils either from culture or from a study of the tonsils after their removal, but these studies give no substantial aid to the clinician in the problem of deciding whether the tonsils in a given case are a menace to the child's health. As no laboratory test is available to determine whether the tonsils are beneficial or harmful to the child, the clinician's decision must rest on his own experience, on his estimate of all the factors that contribute to the child's well being and on the statistical experience of others. Though one would like to apply rigid scientific standards for evaluating the significance of the tonsils in the development of the child, it is quite obvious that such standards are not known and one must resort to clinical investigations. In approaching the clinical study of this problem one encounters numerous pitfalls which make one wonder whether the clinical and statistical studies recorded present the true picture of the tonsil problem. Selkirk and Mitchell⁷ have pointed out that it is difficult to evaluate results in tonsillectomized children because of the variables that exist. The numerous surveys that have been made are based on the accumulation of data which are not obtained by the same methods, so that one must question the real value of such conclusions. When separate and intensive studies of a single symptom in relation to tonsillectomy have

been made, more reliable results have been obtained. Whatever clinical methods are employed, it is essential that control studies should be made simultaneously with those whose tonsils have been removed. For a fair comparison, similar age groups must be utilized and uniformity in the method of examination and follow-up

sequence and the number of their respiratory infections over a period of years. If the expected development in the group in which the tonsils were removed follows a trend significantly different from the group in which the tonsils were not removed, it might be assumed that the presence or the absence of the tonsils has some influence on the physical development of the child. Such studies have been undertaken to determine whether certain infections are lessened by the removal of the tonsils. With no true normal group available, my associates and I endeavored to compare children of like age and environment whose tonsils were removed with a similar group that presented the same indications for their removal but on whom no operation was performed.

THE PRESENT STUDY

Consideration has been given to the common infections of the upper respiratory tract, tonsillitis, the common cold, otitis media and cervical adenitis. The pulmonary infections bronchitis and pneumonia have been investigated and the various manifestations of rheumatic infection have been recorded. Several reports have been made on a large series of children and on control groups in which these various complaints have been followed for a period of ten years.⁸ From these studies it is noted that tonsillitis is a common complaint in young children. Approximately 38 per cent of the 4,400 children utilized in the study were subject to repeated attacks of tonsillitis (at least two febrile attacks a year) during the first seven years of life. Tonsillectomy was advised for all 4,400 children for various reasons but only half of the group submitted, and none of the children in the control group of 2,200 children were operated on during the succeeding years. As is indicated in chart 1, the incidence of sore throat was decidedly lessened during the first three years following the operation and then increased somewhat during the next seven years, but the trend was decidedly downward. In the group in which the operation was not done attacks of tonsillitis recurred with only a slight decrease in frequency during the same years in which the children who were operated on showed a

Chart 1.—Tonsillitis and sore throat among 2,200 tonsillectomized and 2,200 nontonsillectomized children.

must be observed in the two groups. Recognizing the difficulties in obtaining genuine control material, it is still possible to get a fair opinion as to the trend of the child's reaction to certain symptoms. Utilizing Yule's formula for determining whether the variation in the trends is significant or not offers some help in evaluating the significance of the tonsils with reference to certain pathologic conditions.

It is generally accepted by physiologists and by clinicians that normal and uninterrupted growth and development in a child requires a sound body at birth. Adequate food intake fortified with the necessary minerals and vitamins is essential during the first few years of life. Acute and chronic infections are known to halt or to retard the development of the child. To minimize the number and the severity of the infections in infants and in young children, specific protective vaccinations are given. Other precautions in protecting the child against infection are taken that might be termed social or environmental. Severe or repeated infections in the nasopharynx and adjoining organs are known to interfere with the uninterrupted development of the child. It therefore seems logical to improve, if possible, the zone in which the infections usually originate. The tonsils and adenoids are not only in this zone of frequent infection but are frequently the victims when pathogenic organisms gain entrance into the nasopharynx. Sufficient clinical evidence is available to show that the tonsils may impede the development of a child either through hypertrophy or as a reservoir of infection. Experience again and again has shown that enucleation of such tonsils removes the focus of infection and permits the growth and the developmental process to proceed without further handicap. In such instances it seems quite certain that the tonsils were a liability to the child and their removal was highly desirable. Can one, however, deduce from these occasional cases that normal tonsils encourage infections of the throat and therefore share with the infections themselves a deterring influence on the child's development? Again mindful of the fact that no convincing scientific evidence is at hand to explain the part the tonsillar tissue plays in the economy of the child, it becomes necessary to follow the development of a group of children to adolescence, recording the

Chart 2.—Colds (four or more a year) among 2,200 tonsillectomized and 2,200 nontonsillectomized children.

lessened incidence. When one compares the incidence of this infection in the two groups it is obvious that the common ailment termed tonsillitis or sore throat occurred less frequently in the cases in which the tonsils had been removed. In other studies, notably those of Selkirk and Mitchell,⁷ similar results were obtained as far as this complaint was concerned.

8. Kaiser, A. D.: The Relation of Tonsils and Adenoids to Infections in Children, *Am. J. Dis. Child.* 41: 568-581 (March) 1931.

The common cold with its unpleasant complications has frequently influenced physicians and parents to remove the child's tonsils and adenoids, hoping that fewer colds will develop following the operation. It was noted that the incidence of head colds (chart 2, four colds or more a year) occurred with about

Chart 3.—Otitis media (purulent) among 2,200 tonsillectomized and 2,200 nontonsillectomized children.

equal frequency in the two groups under observation. Approximately 42 per cent of the children were subject to this repeated infection up to the age of 7 years. Following the operation for a period of three years the surgically treated children enjoyed greater freedom from colds than those who did not receive surgical treatment. During the next seven years of observation the children who were operated on actually had more colds than the group who were not. Considering the entire ten year period it must be concluded that the children who were operated on showed only a slight advantage over the children who were not, an advantage which cannot be considered statistically significant. It is quite likely that removal of the adenoids benefited the younger children but as the children advanced in years the adenoid tissue retrograded, so that the children who were not operated on were likewise benefited. Though the trend as far as frequent colds are concerned is downward as the child grows older, there is insufficient evidence to show that the removal of the tonsils is solely responsible for this decline in incidence.

Utilizing the same group for the effect of tonsil and adenoid removal on the incidence of purulent otitis media, we noted that 15 per cent of the children who were subsequently operated on had suffered from purulent otitis media before the ages of from 5 to 7 years, while in the control group 12 per cent were likewise affected. During the three year period following tonsillectomy nearly twice as many children who were not operated on had purulent ear infections, but during the next seven years these children fared as well as and even a little better than those who were operated on. It seems quite certain that ear infections are somewhat influenced by age, for regardless of the presence or absence of the tonsils this type of infection becomes less frequent after the eighth year of life. Again it seems probable that the removal of the adenoids was of distinct benefit to the younger children who were subject to ear infections. Once a middle ear infection in the mastoid in tonsillectomized children as in those whose tonsils and adenoids have not been removed. Undoubtedly catarrhal otitis media that leads to impaired hearing is frequently relieved by adenoidec-

tomy in early childhood, but from a study of this group, as chart 3 indicates, the tonsils have no constant relation to infections in the ear.

Cervical adenitis is a common infection in childhood. In each group of this study 15 per cent of the children had definite enlargement of the cervical glands before the ages of 5 and 7 years. Only children in whom there was a visible enlargement of the cervical glands have been considered. In some children this evidence of infection was acute, while in others the enlargement lasted for weeks or for months. During the three year period following tonsillectomy the incidence of cervical adenitis in the children who were operated on was 5 per cent as compared to an incidence of 14 per cent in the children who were not. Over a longer period of time a number of the tonsillectomized children showed a recurrence of cervical adenitis, accounting for an incidence of 7 per cent at the end of ten years, while among the children used as controls the incidence of this complaint was 14 per cent. The statistical evidence in this study as well as in other reported studies shows a significant favorable trend for the relief of this complaint in the groups in which a tonsillectomy had been done.

Though the presence or the repeated occurrence of infections of the upper respiratory tract in children serves as the most common indication for the removal of the tonsils, the subsequent incidence of pulmonary infections must be considered. Pulmonary infections occurred more frequently in children in the first five years of life than in the next ten years. Such is the usual incidence of these infections. Undoubtedly in our groups some children subject to pulmonary infections were operated on because of this tendency, for more of the children who underwent the operation had repeated attacks of bronchitis and pneumonia before the ages of 5 to 7 years than in the group of children who were never operated on. In spite of this, the trend was definitely for more pulmonary infections in the tonsillectomized group over the ten year period than for the control children. It seems that the absence of the tonsils either increased the chances of developing bronchitis

Chart 4.—Cervical adenitis (acute and chronic) among 2,200 tonsillectomized and 2,200 nontonsillectomized children.

and pneumonia or else the tonsillectomized group represented the more susceptible individuals and the operation was not responsible for the increased incidence of pulmonary infections.

Chronic or recurrent diseases such as tuberculosis, asthma, nephritis, diabetes and rheumatic fever are known to influence the development of the child. In the prevention or the control of these diseases the role of the tonsils must be considered.

Statistical studies have been made on 500 children from 5 to 14 years of age in whom positive signs of tuberculosis existed. All the children gave a positive reaction to the intradermal tuberculin test and showed roentgenologic evidence of tuberculosis. An analysis of this group with reference to the presence or absence of the tonsils and the age at which they were removed

Chart 5.—Pulmonary infections (bronchitis and pneumonia) among 2,200 tonsillectomized and 2,200 nontonsillectomized children.

showed that no significant relationship could be demonstrated between the development of tuberculosis and the presence or the absence of the tonsils. When tuberculous cervical adenitis is considered it is quite clear that the tonsils are frequently a source of entrance for the tubercle bacillus and the removal of the tonsils may reduce the incidence of this tuberculous manifestation.

Children with nasal allergy, allergic involvement of the sinuses, allergic bronchitis and allergic pneumonia are not favorably influenced by tonsillectomy. Bullen⁹ in a study of 2,000 children concluded that tonsillectomy does not aid in improving the results of treatment of nasal or of pulmonary manifestations of allergy. Recently Hansel and Chang¹⁰ reached similar conclusions. They caution against the removal of tonsils and adenoids in allergic children during attacks of hay fever and against recourse to tonsillectomy with the idea of alleviating allergic symptoms.

Rheumatic manifestations in children have long been associated with infection in the tonsils. This relationship received the support of Osler in 1902, who stated "Special stress has been laid upon the tonsils as the point of entrance of the infections, as it has long been known that tonsillitis was a very frequent initial symptom. Indeed some have gone so far as to say that there is always a primary infective trouble in the lacunae of the tonsils, to which the rheumatic fever is secondary, arising from the absorption of microbes or their products." Subsequent writers stressed this relationship, which gave rise to the common dictum "the tonsil, the portal of entry of rheumatic infection." This resulted in a form of speech that became almost a platitude in the course of medical literature to the degree that it was accepted and dispensed with the regularity of an acquired habit and no doubt frequently without stopping to inquire how far it agrees with personal experiences and recurring clinical material. The various attempts to evaluate the relation of the tonsils to infections included rheumatic manifestations. These studies emanating from various parts of this country and from

England agree that there is no justification in the statements that were accepted for more than twenty-five years. No unanimity exists in these studies, owing in part to a different approach, but in general it has been shown that any rheumatic manifestation may develop in a child whose tonsils have been removed prior to the first evidence of rheumatic disease. There is also complete agreement in the statement that recurrent attacks of rheumatic disease are as likely to occur in children whose tonsils have been removed as in those in whom they are still intact. There is, however, some difference of opinion as to the influence of the tonsils on the cardiac complication and on the mortality in this disease.

The survey made in Rochester gives a fair idea of the incidence of rheumatic manifestations in two large groups of children. It is noted that chorea seems not to be influenced favorably by tonsillectomy; in fact, primary attacks were somewhat more frequent in tonsillectomized children. Rheumatic fever occurred somewhat less frequently in the tonsillectomized children. This difference may be explained by the lessened incidence of throat infections in the children who were operated on. The mild rheumatic symptoms termed muscular or growing pains occurred frequently in both the tonsillectomized and the control group. Though the children who were operated on had somewhat less evidence of trouble, the difference in the two groups was not statistically significant. Rheumatic carditis was studied in the 4,400 children in a similar manner to that in which the other rheumatic manifestations were studied. The incidence of carditis did not differ much in the two groups. During the ten year period in which these children were observed, it developed that 1.1 per cent of the children contracted rheumatic carditis following tonsillectomy, while among the children whose tonsils were not removed 1.3 per cent contracted the same lesion. The difference is not significant. It would appear from the figures that tonsillectomy did not have much to offer either in the prevention or in the control of rheumatic infection. A further possible relationship of the tonsils to rheumatic infection was sought in studying the outcome of a group of rheumatic children. This observation was made on a group of 597 children who had developed their first attack of rheumatic infec-

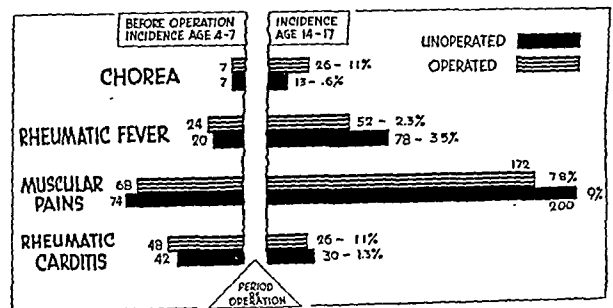

Chart 6.—Rheumatic manifestations before and for ten years after removal of tonsils of 2,200 children and for a similar period among 2,200 nontonsillectomized children.

tion between the ages of 5 and 10 years. All these children either were observed for a period of ten years after their primary attack or succumbed to the disease during this period.

In table 1 it is noted that these children could be divided into three groups: those whose tonsils were in at the time of the primary attack and remained in during the five year period of observation, those whose

10. Hansel, F. K., and Chang, C. S.: *Relation of Allergy and Tonsillectomy in Children*, *Arch. Otolaryng.* 31: 45 (Jan.) 1940.

tonsils were out at the time of the initial attack and those whose tonsils were in at the time of the initial attack but were removed subsequently during the five year period of observation. The mortality rate (table 2) is distinctly higher in the group of children whose tonsils were not removed. Though the recurrences were about the same in the three groups, the children who were operated on appeared to be somewhat safeguarded. A similar experience has been commented on by several clinicians, and recently Allan and Baylor¹² presented evidence to substantiate that position.

In reviewing the several studies made on the relationship of the tonsils to rheumatic disease in children it becomes evident that the surgical treatment of the tonsils, regardless of the age of the child, offers no certainty in preventing this infection and apparently does not reduce the number of recurrences. The clinical improvement in many cases has justified the operation, and the somewhat meager statistical data at hand in the Rochester study suggests that fatal carditis was noted less frequently in the tonsillectomized group.

The incidence and the complications occurring in the common infectious diseases of childhood were studied

the nutritional development even if the other factors essential to good nutrition are assured a child.

Such disturbances as recurrent vomiting attacks and chronic anorexia are known to influence the development of the child unfavorably. The underlying causes of these manifestations are not always obvious. When they exist the tonsils are frequently incriminated,

TABLE 1.—Incidence of Recurrent Attacks of Acute Rheumatism with Reference to Removal of Tonsils in 439 Children Observed for Five Years

Age of Children at First Attack	Number in Whom First Attack Developed Before Tonsillectomy	Number Who Had Recurrent Attacks	Number in Whom First Attack Developed After Tonsillectomy	Number Who Had Recurrent Attacks
Under 5 years.....	36	11-31%	2	1-50%
From 5 to 10 years...	104	42-41%	22	10-45%
From 10 to 15 years..	151	30-33%	88	19-21%
From 16 to 17 years..	25	8-32%	11	4-36%

even before a careful search is made for other etiologic factors. Undoubtedly chronic infections in the tonsils can bring about these symptoms, for there is abundant clinical evidence that recurrent or cyclic vomiting is sometimes relieved after the tonsils of these children have been removed. Marked improvement in the appetite likewise has been known to develop when presumably infected tonsils have been removed. It does not follow, however, that tonsillectomy always assures a child freedom from the vomiting habit nor does the appetite promptly improve. A careful analysis of these complaints in a group of children before and after tonsillectomy showed that after tonsillectomy approximately 50 per cent were relieved of the attacks of periodic vomiting that had existed prior to the operation. In the case of anorexia that had been present for some time before a tonsillectomy was performed, somewhat less than 50 per cent showed improvement in appetite following the operation. In attributing the improvement to tonsillectomy one must not overlook the fact that such complaints as recurrent vomiting and anorexia disappear even when the tonsils are not removed. Certainly in some individuals diseased tonsils are the direct cause of these digestive complaints.

Impairment of hearing and irregularities in speech have been ascribed to obstructive lymphoid tissue in

Chart 7.—Diphtheria, scarlet fever and measles before and for ten years after removal of tonsils of 2,200 children and for a similar period among 2,200 nontonsillectomized children.

in the tonsillectomized and nontonsillectomized groups. In pertussis the presence or absence of the tonsils made no difference. The same situation existed with measles. Diphtheria showed a lower incidence in the tonsillectomized children, but the incidence was low in both groups, probably owing to immunization. Scarlet fever occurred somewhat less often in the tonsillectomized children, but the difference was not significant. In a study of 267 scarlet fever patients in the hospital it was found that more complications developed in the children whose tonsils had not been removed.

The proper development of the child may be interrupted by recurrent infections or may be interfered with when normal physiologic processes such as nutrition, digestion, speech, hearing and mental development are impaired. There is abundant clinical and statistical evidence to show that either hypertrophied tonsils or infected tonsils may impair the child's nutrition. Following removal of the tonsils in these instances the nutrition of the child promptly improved. When, however, the procedure was applied to a large group of children on whom a prophylactic tonsillectomy had been performed, there was no evidence that the tonsillectomized children demonstrated a superior nutritional state. Sufficient evidence is available to show that chronically infected tonsils may definitely retard

TABLE 2.—Effect of the Tonsils on Outcome of Rheumatic Infection in 597 Children Followed for Ten Years

Tonsils	Number	Died	Recurred	No Recurrence
Remained in.....	156	13%	46%	41%

the nasopharynx. Hearing defects other than those produced by infection in the middle ear may be due to lymphoid obstruction of the eustachian tube. The tonsils are seldom responsible for impairment of hearing. The adenoids frequently are the cause of trouble and removing them may promptly relieve this condition. Speech irregularities have been improved in cases in which hypertrophied tonsils and adenoids have been removed, but there is no evidence that the tonsils are a disturbing factor in any large number of children with speech defects.

12. Allan, W. B., and Baylor, J. H.: Bull. Johns Hopkins Hosp. 62: 111-123 (Aug.) 1938.

There is undeniable evidence that the child population of our country has experienced better physical development with fewer interruptions due to mild and prolonged illnesses in the last three decades. Not only has the infant mortality been materially reduced but fatal illness in children of school age is less likely to occur. It is true that this saving of child life and improvement in the general health of the child has come during the period of widespread surgical treatment of the tonsils. It has even been suggested that removing the tonsils in from 30 to 50 per cent of the urban children of our country has played a major part in attaining this favorable situation. One cannot, however, lose sight of the fact that notable advances have been made in the science of nutrition during this period. The application of these discoveries has contributed appreciably to improving the nutritional state of the growing child. Likewise in the fields of bacteriology and immunology advances have been made which have greatly reduced the hazards of certain diseases, notably diphtheria, syphilis and pertussis. Perhaps of even greater importance to the child has been the widespread application of public health procedures such as pasteurization of milk, the safeguarding of water supplies and the refrigeration of foods. Health education in the schools, by volunteer and official health agencies and the utilization of the press and the radio, has reached many children and parents who formerly were kept in ignorance of the factors that safeguarded health. Due consideration must be given to all these contributing factors in assigning the reasons for the improved health of the children of America. Because of these various improvements in child care that have been made available during the last three decades, it becomes more difficult to assign to the tonsils the particular part that they play in the economy of the child.

CONCLUSIONS

The tonsils have assumed an important role in the economy of the child during the last thirty years. The beneficial results following tonsillectomy in selected cases inspired this procedure on a large percentage of children often without a good reason.

Follow-up studies on tonsillectomized and nontonsillectomized children were undertaken to show the trend of certain complaints over a ten year period in the two groups and to note the effect of the tonsils on the physical development of the child.

It was shown that markedly hypertrophied tonsils and tonsils that are repeatedly inflamed giving rise to attacks of tonsillitis and cervical adenitis frequently do impair normal physical development. When such a condition exists after the age of 4 years it is advisable to have the tonsils removed, with the expectation that at least 50 per cent of the children so treated will be materially improved.

Such infections as the common cold, otitis media, sinusitis and laryngitis may unfavorably influence the child's normal development. It cannot be demonstrated that the tonsils are often a causative factor in these infections; consequently tonsillectomy does not offer a solution for their eradication save in exceptional cases.

It could not be shown that the incidence of such diseases as bronchitis, pneumonia and tuberculosis was reduced in tonsillectomized children. The tonsils are not often responsible for pulmonary infections.

Rheumatic disease and nephritis constitute serious handicaps to a child's normal development. Recent studies show that the tonsils play a less significant role

in the causation and treatment of these diseases than was formerly supposed. However, a reduction in the number of throat infections following tonsillectomy has a beneficial effect in the rheumatic subject.

There has been a significant decline in the mortality and morbidity rate of children during the last three decades. There has also been an improvement in the physical development of children in America. The application of the new discoveries in the field of nutrition, immunology and sanitation has contributed much to this favorable situation. When proper consideration is given to these factors it is evident that the tonsils are not as great a menace to a child as has been frequently suggested.

There is substantial evidence that in about 20 per cent of the children the tonsils are either hypertrophied or diseased and therefore have an unfavorable influence on the physical development of the child. Such tonsils should be removed.

16 North Goodman Street.

RESULTS OF CONSERVATIVE APPLICATION OF X-RAY TREATMENT IN CHRONIC LEUKEMIA

A NOTE OF OPTIMISM

WILLIAM P. MURPHY, M.D.

BOSTON

Forkner¹ has written "It is now almost a hundred years since the classical description of leukemia yet today we know almost nothing about its cause or its specific treatment." The truth of this statement will be evident from even a brief review of the more recent literature on the subject or of almost any series of records of patients treated according to the customarily applied technics.

The rather general tendency toward pessimism on the part of the medical profession in respect to the possible benefits to be derived from treatment of a patient with leukemia has developed, and is perhaps in part justifiable, because of the ineffectiveness of therapy in the acute and atypical leukemias which is assumed to apply to all leukemias and because of the failure of statistical studies of case records to have demonstrated that the life span of the patient with chronic leukemia has been appreciably lengthened as the result of treatment. Although the measure of the value of therapy of an illness on the basis of its effect on duration of life has a dramatic appeal it may blind us to the importance of treatment, particularly of the patient with a chronic illness, in respect to his economic and social status, general health and comfort.

In 1924 Minot, Buckman and Isaacs² reported data which showed little difference between the average duration of life of seventy-eight patients with chronic myelogenous leukemia treated by x-ray irradiation and fifty not irradiated. The former group lived an average of 3.5 years after the first symptoms, the latter slightly

From the Medical Clinic of the Peter Bent Brigham Hospital. Dr. Merrill C. Sosman directly supervised the x-ray therapy, and Miss Isabel Howard made numerous blood counts.

2. Minot, G. R.; Buckman, T. E., and Isaacs, Raphael: *Chronic Myelogenous Leukemia: Age Incidence, Duration and Benefit Derived from Irradiation*, J. A. M. A. 82:1489 (May 10) 1924.

more than 3.0 years. In the same year Minot and Isaacs³ published similar data concerning chronic lymphogenous leukemia but found no essential difference in the average duration of life in irradiated and nonirradiated patients. A group of eighty patients composed of fifty irradiated and thirty nonirradiated lived an average of 3.45 years after the first symptoms. It was concluded that both groups were benefited symptomatically by irradiation, the myelogenous group benefiting by an average of 1.6 years of efficient life whereas in the lymphogenous group the efficiency of the patient was increased strikingly in only 10 per cent. The latter authors quote Klewitz and Schuster⁴ and Brandt⁵ as reporting the average duration of life in chronic lymphogenous leukemia to be about two years.

Hoffman and Craver⁶ reported the average duration of life after the onset of the disease to be 3.36 years and after the beginning of treatment 2.62 years for eighty-two patients with chronic myelogenous leukemia. These authors were, however, somewhat more optimistic in regard to the other benefits to be derived from x-ray treatment and concluded that "The actual duration of efficient life after beginning irradiation averaged 2.13 years, varying from eight months to 5.66 years. The radiation treatment causes an average increase of about ten months in the duration of efficient life—a period of efficiency and usefulness that the patient otherwise could not hope to enjoy."

Arendt and Gloor⁷ reported even more favorable results from therapy of both forms of chronic leukemia. The average duration of life in thirty-nine cases of chronic myelogenous leukemia was four years, and of even greater importance perhaps is the occurrence in their group of a greater number of patients living more than four years.

Although Allen and Dickey⁸ have not discussed duration of life, they have been greatly impressed with the possibility of improving the patient's general condition. Their attitude is well expressed in the following sentence: "Any procedure which will increase the length of a remission, raise the degree of the patient's efficiency during a remission or prolong useful life in myelogenous leukemia deserves consideration."

This small group of references to literature dealing with the effect of therapy on the prognosis in respect to prolongation of life and symptomatic improvement tells essentially the entire story of the results of the treatment of chronic leukemia to the present time. Treatment in myelogenous leukemia has been primarily that of periodic exposure of the spleen and (or) the long bones to rather massive doses of x-rays, except in the groups reported by Forkner and Scott⁹ and Arendt and Gloor,⁷ in which the use of arsenic was emphasized. Little originality has been shown in respect to the method of application of treatment and little effort has been made to keep the disease process under control. Arendt and Gloor⁷ have given arsenic in some form

more or less continuously between relapses, which were then controlled by x-ray therapy as the need arose. Allen and Dickey⁸ have emphasized the importance of following the patient's condition carefully by means of frequent analysis of the condition of the blood and by saliva leukocyte counts, but they state that, "As a general rule, a series of treatments should be initiated only when the patient's general condition is poor and his efficiency low." This method of determining the use of treatment has been subscribed to by Minot, Buckman and Isaacs,² Hoffman and Craver,⁶ Forkner¹ with reservations and Jackson,¹⁰ who states that treatment of chronic myelogenous leukemia should be withheld until such time as the patient's symptoms appear to call for alleviation. In discussing the treatment of chronic lymphogenous leukemia, Jackson¹⁰ makes the comment: "As with chronic myelogenous leukemia, irradiation of the spleen or chest, preceded by blood transfusions if there is a coexisting anemia of moment, is the treatment of choice. It is very questionable, however, whether there is any advantage in treating those patients who are symptomless. The details of the x-ray therapy should be left to the radiologist in charge . . ."

This attitude toward the use of x-ray therapy is that which has largely influenced the regulation of treatment up to the present time and which is probably largely responsible for the belief held by many clinicians that the patient with chronic leukemia is not in better condition with a low than with a high leukocyte count. It is quite obvious that with the method of therapy often employed such might be the case. Massive x-ray dosage is applied over the spleen at a time when the patient is weakened, often suffering from anorexia and nausea and with a high leukocyte count. The therapy may increase the anorexia and nausea, the leukocyte count may drop rapidly even to a subnormal level and the hemoglobin and erythrocyte levels may drop, which increases the feeling of weakness and malaise so that it may take days, weeks or even months to recover from the effects of treatment, at the end of which time and just when the patient has begun to feel fairly well his leukocyte count is again rising, symptoms returning and he is put through another third degree of treatment. And thus many of our patients go through a series of relapses and remissions feeling more disturbed than relieved by therapy, dreading each successive series of treatments more and more, frequently to the point of avoiding the physician's check-up until it is too late to hope for much benefit. The periods during which the patient experiences a feeling of well being of sufficient degree to allow the pursuit of normal activity are short and generally progressively shorter, and the periods of sickness during and following x-ray therapy either in or out of a hospital are discouraging and expensive ones. Exceptions to this course do occur. Spontaneous remissions of longer or shorter duration may be experienced by the patient with either form of leukemia with and without therapy, but these are not the rule and do not affect the course of the illness of the majority of patients.

With these facts in mind and after having observed the unfavorable general condition of a group of patients with chronic leukemia treated in the generally accepted manner, it seemed desirable to consider wherein this form of treatment was at fault and then to correct these faults as far as possible.

The most obvious and serious fault appeared to be that of allowing the patient to develop repeated relapses during which the disease process has progressed, followed by intensive treatment at a time when the general condition is poor. The well treated patient with diabetes or pernicious anemia is not permitted to omit treatment until severe acidosis or relapse occurs but is maintained constantly in as nearly a normal condition as is possible. Why is it not equally logical to prevent relapses and to maintain as nearly as possible a normal condition for the patient with chronic leukemia? In order to accomplish this the patient is advised to report each month for a blood examination. If the leukocyte count shows a tendency to rise during successive counts or if it has reached a level of about thirty to forty thousand, one x-ray treatment is given.

consultation with the roentgenologist, but the patient's physician will constantly guide the course of therapy because the roentgenologist may not be equipped to do blood counts and may not be so familiar with the patient's general condition.

The size of the x-ray dose and the site to be treated offered another problem for consideration. Severe anorexia, nausea and vomiting frequently follow massive therapy applied over the spleen, to a mass of lymph nodes or over the chest, and yet a similar dose over the long bones was often less disturbing to the patient but the effect on the leukocyte count, mass of lymph nodes or spleen was essentially the same. It would appear to be logical therefore to avoid the disturbing upset of the patient by the use of smaller dosage, provided an equally good effect can be produced. By apply-

If the rise has been gradual the patient returns for a leukocyte count at the end of a week; if rapid or if the count has risen above about forty thousand a count is done on the day following treatment. If in either case the leukocyte level has not dropped sufficiently, another treatment is given. In each instance an effort is made by this means to maintain the leukocyte level as near normal as possible constantly and never to allow it to rise above forty thousand. X-rays applied in this way rarely produce distressing nausea and the patient's condition remains rather uniformly good except as it may be influenced by intercurrent infections or other complications. Care must be taken to avoid too great a drop in the leukocyte count as the result of overdosage with x-rays. This will rarely occur if each treatment is preceded by a leukocyte count, and if there is then any question with regard to the advisability of further exposure an interval of a few days or a week may be allowed, at the end of which another count is done. The exact treatment which is to be given will be decided in

ing this small dose over a large part of the body surface it was found possible to do this and thereby to avoid on most occasions the disturbing post-treatment effects. Mild anorexia and nausea have followed treatment of the very sensitive patient and on rare occasions of any patient, but a severe unpleasant or incapacitating reaction has rarely occurred. The use of small dosage and the application of the x-rays over the greater part of the body from a distance, so-called teleoroentgen therapy, have both been advocated previously and both are now being used for the treatment of leukemia in several clinics, but their value as opposed to the massive dose method has not been widely enough recognized and the method has not come into general use.

The principles here set forth for the treatment of the patient with chronic leukemia have been applied as far as possible to a small group of patients and the results as far as age, sex and duration of life is concerned are shown in tables 1 and 2. For comparison with the groups shown in tables 1 and 2 there is pre-

sented in tables 3 and 4 groups essentially similar but treated largely by massive dosage, periodically as symptoms of progression of the disease state indicated without the attempt at complete control of progress as in the two former groups. There is not a sharp line of distinction between the method of treatment or follow-up in certain individual cases in the two groups and one might question the decision to include them in one table as opposed to the other. For example, patient 6 included in table 1 lived on a farm in Canada which made it difficult for him to return sufficiently often for treatment to be given to maintain the blood in a satisfactory state. On the other hand his x-ray therapy was given in small doses over the entire body except

far more disturbing than the symptoms of the disease. Anorexia and mild nausea are almost constant during its use, severe nausea and diarrhea frequent occurrences. An example of its effect is found in a case that came to my attention after approximately three years of arsenic therapy with a high leukocyte count. Anorexia and mild nausea were present almost constantly during this time, the patient being scarcely able to eat a meal and having lost 40 pounds (18 Kg.) during the last year of treatment. Following a few x-ray exposures by the "spray" technic the leukocyte count dropped to a normal level, the patient's appetite improved immediately and he regained within a few months the 40 pounds lost. Solution of potassium arsenite may be of value

for two exposures to the cervical region at a time when the glands in this region were greatly enlarged. His death followed a severe hemorrhage from the gastrointestinal tract. This occurred during the middle of winter, 20 miles from his physician, who found it impossible to give him a transfusion of blood. Even though he was then 72 years of age, life might have been prolonged had circumstances been different.

Arsenic in the form of solution of potassium arsenite has been used from time to time in several of the group of patients with myelogenous leukemia of table 4. The effect has been to decrease the leukocyte count from the height of the peak during relapse, as was shown to be possible by Forkner and Scott,⁹ but there has been no evidence that it is possible to maintain the leukocyte count at a low level for a longer period of time than is the case following x-ray exposure. The most striking effect of the arsenic has been to upset the patient to such an extent that the treatment was

for the patient who does not have access to x-ray therapy but is probably less desirable than x-rays when this form of treatment is available.

In practically all instances, the patients listed in tables 1 and 2 have had leukocyte counts done frequently and an effort has been made to control these levels and the patient's general condition by x-ray treatment at intervals as indicated. Each treatment, with rare exceptions, since early in 1934 has been applied over the entire body, alternately front and back, supplying about 50 to 60 roentgens per dose. In general the treatment may be described as follows: 200 kilovolts, 100 cm. distance, 0.5 mm. of copper filter, spray technic.

Data concerning seven patients with chronic lymphogenous leukemia treated in the approved manner are shown in table 1, and concerning ten patients by the older method in table 3, a total of seventeen. Data concerning nine patients with chronic myelogenous leukemia treated in the approved manner are shown in

table 2, and concerning eleven patients by the older method in table 4, a total of twenty. The number of cases reported in any of the groups is too small to allow the data to be considered statistically, and as this report is not concerned with the analysis of leukemia in general they will not be discussed in detail. It is of

Chart 1.—Course of the leukocyte count in case 3 of table 1 during five years' observation before x-ray treatment was started.

interest to note, however, that myelogenous leukemia appeared at an earlier age in many instances than did the lymphogenous form; that of the seventeen lymphogenous eight were male, nine female and of the twenty myelogenous eight were male, twelve female; that the basal metabolic rate was increased more uniformly in those in whom the test was made in the myelogenous than was the case in the entire lymphogenous group; and that the most commonly observed evidences of the disease in its earlier stages were enlarged lymph nodes or a mass in the left abdomen; continuous or intermittent fever of unknown origin; anorexia, nausea or vague gastrointestinal disturbance; and definite, often striking loss of weight. Pulmonary tuberculosis pre-

Chart 2.—Course of the leukocyte count in the same patient as of chart 1 is shown during five years of treatment with x-rays at intervals necessary to maintain the leukocyte level below about 40,000. The arrows indicate the time of x-ray treatment, the figure beside the arrow the number of exposures.

ceded the onset of leukemia in two of the myelogenous groups. A pneumothorax had been produced on the right side in patient 12 of table 2 but after four years of leukemia and shortly before death x-ray examination showed extensive involvement of the left lung. A postmortem examination was not made. Patient 37

of table 4 developed leukemia while in a tuberculosis sanatorium. At postmortem examination the tuberculosis was described as healed. Three instances of myelogenous leukemia were basophilic (table 2, cases 14 and 16; table 4, case 31). Uric acid determinations were made on the blood of four of the lymphogenous group with the results 3.3, 3.6, 5.2 and 5.7 mg.; and in five of the myelogenous group with the results of 3.4, 4.6, 6.0, 6.2 and 6.7 mg. per cubic centimeter.

It is difficult to compare the longevity of the two groups with either form of leukemia with each other or with the reports from the literature previously mentioned, but in general the showing of the group in table 1 is definitely better than that of those in table 3. The duration of life has been five years or longer in four patients of the first group, whereas only one of the second group lived five years or longer. Taking into consideration the fact that all but two of those in table 1 are living and in good condition at the present time, and allowing for the possibility that the disease may be present in mild form in some of these, the result compares favorably with that of previously reported groups. But even though one may question whether or not much has been gained in respect to length of life, the members of the group shown in table 1 have during

Chart 3.—Course of the leukocyte count in case 21 of table 3 during treatment at intervals by massive dosage of x-rays. The arrows and figures beside them indicate the time given and number of x-ray exposures.

life remained essentially well and able to carry on their daily duties without interruption except during the occurrence of a complicating illness. The female patients have continued with their household duties, patient 7 has continued actively with his ministerial duties and patient 3 has returned to his former occupation as a bus driver after having been relieved from duty for several years because of severe rheumatoid arthritis which antedated the leukemia. The arthritis has been completely controlled so that for three or four years hard labor has been possible without undue fatigue. The course of this patient's leukocyte levels during a period of five years before treatment was started is shown in chart 1 and for five years under treatment in chart 2. Since x-ray therapy was started the leukocyte level has been maintained below 40,000 by repeated exposures as shown in chart 2. In contrast to this patient's course is the irregular swing of the leukocyte levels of patient 21, table 3, whose clinical course was equally unstable (chart 3). The periods of remission with anything approaching normal vigor were short, a matter of a few weeks, rarely months, in the entire group shown in table 3.

The story of the two groups with myelogenous leukemia is not unlike that which has been described for the

lymphogenous groups except that the duration of life was not so long in either group (tables 2 and 4); but even so that of the patients of table 2 treated in the approved manner is longer on the average than that of the group in table 4 or of several of the series reported in previous literature. The course of the disease in the patients of table 2 has not in each instance been so smooth as that of the group with lymphogenous leukemia (table 1) and yet the majority have been remarkably well and practically throughout the duration of their life have carried on their normal duties except when handicapped by intercurrent disease. An example of the course of the leukocyte levels in a patient of this group is that of patient 13, table 2, shown in chart 4. Although this patient lived only three and a half years he continued actively at work as a model maker in a brass foundry and stopped only when a few days before his terminal illness he complained of severe abdominal and head pain. The urine suddenly became loaded with sugar and he became comatose and died a few days after admission to the hospital for the first time. At post-mortem examination cerebral thrombosis was given as the cause of death. In contrast to this patient's excellent health and control throughout life there is shown in

severe upper respiratory infection, herpes zoster and pneumonia prevented return at the proper interval on three occasions.

Patient 11 of table 2 received treatment only at the beginning of the last five months of her life, having had a spontaneous remission of four years' duration.

Chart 5.—Course of the leukocyte count in case 28 of table 4 as influenced by interval massive doses of x-rays. The arrows and figures beside them indicate the time given and number of x-ray exposures.

Although essentially well during the last five months she died suddenly on the fifth day following a minor operation, apparently from a cerebral embolus. A post-mortem examination was not made. Her case report possibly should not be included in either group but this is done in order that the series may be entirely consecutive and inclusive.

Isaacs¹¹ has suggested that the effect of x-ray irradiation is to be considered as a stimulative one, in small doses causing division and in large doses causing maturation and death of the leukocytes from senility. The results observed in the treatment by the spray technic in relatively small dosage as used in the cases reported in tables 1 and 2 confirms at least to some extent this concept (chart 6). It has been observed

Chart 4.—Course of the leukocyte count in case 13 of table 2 as it was controlled by repeated small doses of x-rays. Each arrow indicates an x-ray exposure supplying approximately 50 roentgens applied by the spray technic.

chart 5 the pendulum-like rise and fall of the leukocyte levels of patient 28, table 4, who lived the same length of time from the onset of the disease but who was at almost no time well, was unable to resume any of his normal activities and spent much time in the hospital. As in the lymphogenous group, most of those of table 4 were more sick than well whereas most of those of table 2 lived a rather comfortable life.

The regularity of recurrence of the periods of marked increase in the leukocyte levels which commonly occurs in patients not completely controlled is well illustrated in chart 5. The interval between the peak of the rise in each relapse was approximately three months throughout the duration of the illness. The duration of this interval varies from patient to patient, but it is likely to remain rather constant in a given individual and may be influenced to some extent by the treatment used.

A six months interval between the several leukocyte peaks was observed in patient 16 of table 2 as shown in chart 6, in whom x-ray treatment was applied by the spray technic but who did not report for observation sufficiently often to allow the leukocyte level to be controlled. Three periods of rather serious illness including

Chart 6.—Course of the leukocytic count in case 16 of table 2. X-ray treatment was given by the spray technic but control was bad because of the patient's failure to return for counts at proper intervals. In the right hand portion of the chart is shown the detail of the leukocyte response to therapy. Each arrow indicates an x-ray exposure supplying approximately 50 roentgens by the spray technic. The figures beside the arrows in the left hand portion of the chart indicate the number of exposures.

in these groups that the leukocyte level has tended to increase, often strikingly, during the few days following initial therapy after a relapse and that the per-

11. Isaacs, Raphael: Maturing Effect of Roentgen Rays on Blood-Forming Cells, Arch. Int. Med. 50:836 (Dec.) 1932.

centage of young or immature cells increases at first, to decrease gradually with a shift to more mature forms as the total leukocyte count drops to a near normal level. In several cases in which the leukocyte counts reached entirely normal levels the differential counts failed to show any immature, although some young forms. With repeated small dosage given as the levels tended to rise, the differential count has in many instances remained remarkably near normal for long periods of time. The nature of the response of the leukocytes to small x-ray dosages and the fact that it is possible to maintain them rather constantly at low levels with repeated exposures to small quantities suggests that chronic leukemia results from a deficiency of some substance necessary for maturation and (or) origination of leukocytes much in the same manner as pernicious anemia results from a deficiency of an antipernicious anemia factor. The deficient factor in leukemia is supplied in some manner by the x-ray exposure in small dosage, probably less satisfactorily by large dosage, which may also act to destroy cells. No doubt there is some more satisfactory means of supplying the "antileukemia" factor than by x-rays which may in themselves injure tissue. Future work should supply this substance, which will probably not be in the nature of benzene or its derivatives, the use of which is to be discouraged because of their known toxic effects, perhaps at times actually precipitating the disease state.

Another point of some interest in these patients is that in case 35, table 4, the leukemia developed after a period of definite exposure to benzene fumes. Cases similar to this have been reported by several authors previously. Two patients had been exposed to and felt keenly aware of the presence of illuminating gas fumes. Patient 13, table 2, worked for several years closely exposed to gas fumes and patient 14, table 2, had noticed leakage of gas from a kitchen range and had become acutely ill from this on several occasions. Several members of both groups had been exposed to some leakage of gas but the majority of patients who have come under my observation showing a leukemia-like blood picture, which might be interpreted as resulting from exposure to either illuminating gas or benzene fumes, have had a more acute course. It is possible that persons highly susceptible to benzene fumes may get sufficient exposure from traces of benzene in illuminating gas to develop the several evidences of disturbance in the blood which may follow exposure to higher concentrations. Further study of the concentration of benzene in canned foods and developed in limited areas from adhesive substances and in the illuminating gas from leaky fixtures may add to our knowledge of the etiology of leukemia and other blood dyscrasias of an atypical form.

SUMMARY

It is proposed that treatment of the patient with chronic leukemia be so applied and regulated that the disease state is kept constantly under control with avoidance of the severe relapses which so frequently occur. The method suggested is the frequent determination of the leukocyte level followed by x-ray exposure sufficiently often to maintain the level as near normal as possible. X-ray therapy is applied in small dosage by the "spray" technic in an effort to avoid severe reactions.

Data particularly recording the duration of life in two small groups of patients with chronic lymphoge-

nous and myelogenous leukemia respectively who have been treated in large part by the method described were compared with data concerning two similar groups treated by the more generally used interval, massive dose method.

Not only is there suggested some advantage in respect to longevity in the former groups as opposed to that of the latter, but the general health and economic efficiency of the patients of the former has been strikingly better throughout the duration of the illness than has been the case in the groups treated by the older methods.

311 Beacon Street.

ABSTRACT OF DISCUSSION

DR. IRVING S. WRIGHT, New York: The chairman would like to ask whether any thought has been given to estimating how long the average patient has the disease before it is discovered. An answer to this question would have to depend on careful histories of individuals who had had repeated blood counts and physical examinations for other causes but which were negative for leukemia so there could be some estimation as to how long the disease was present, or at least when the patient was last known to be normal. I think that might influence to some degree statistics as to years that the patient lived, although it would be a factor that would be constant in both of Dr. Murphy's series.

DR. PAUL REZNIKOFF, New York: I do not see how one can tell how long a patient actually has had leukemia when we know how often leukemia is diagnosed in a routine examination. In fact, very often the patient shows a large spleen that he never suspected. One can determine how long a patient has had symptoms from the time he began his symptoms to the time one saw him and made a diagnosis of leukemia. I feel that most of the patients with acute leukemia have had leukemia for a longer period than they actually admit being sick. Since we do not know the etiology we are forced to treat patients either according to symptoms or hematologic observations or, better, both. I have used a good deal of spray radiation for my patients and I agree with Dr. Murphy that in general it has given more satisfaction than the massive localized therapy. But I feel that, patients differing so, it is important to determine therapy not on the basis of any routine but on what the patient shows at the particular time and how the patient responds to the particular therapy at a given time. I have had some patients whom spray radiation has never helped and even made them sick, although the majority of patients have been able to stand spray radiation much better than they could spot or localized radiation. I have given about 50 roentgens as a rule. X-rays are toxic. One cannot give x-ray therapy over a long period of time without careful check of the patient and his blood count. I believe it is necessary to check not only the white blood cell count but also the platelets and the red cells and hemoglobin. I should like to ask Dr. Murphy whether in his so-called continuous therapy he has had patients who have developed anemia or thrombocytopenia with purpura which he might attribute to the method he used.

DR. CLAUDE E. FORKNER, New York: Leukemia is a disease of unknown cause and without satisfactory treatment. For ten years some workers have been trying to irradiate large areas of the body with so-called spray or teleroentgen therapy. This followed the observation of Levin in 1922 and Minot and Spurling in 1924 that the effect of irradiation on the blood is dependent to a large extent on the square surface of entry of the rays into the organism. It should not be forgotten that not only the favorable but also the unfavorable effects are dependent on these same factors. Spray irradiation is at times useful but it is also dangerous, and especially in leukemia it must be applied with caution. Single doses of 50 or 60 roentgens in some patients will bring about severe leukopenia and thrombocytopenia and will accentuate the anemia. There is marked variation in individuals in their response to a given dose of irradiation. The leukocyte count alone is not a safe guide to follow. The

thorough study of each patient as a whole over a reasonable length of time, taking into consideration all the available information in the history, physical examination and laboratory studies, provides a far better index for selection of cases for appropriate treatment than to use any one factor as a guide. In our present state of ignorance we are not justified in regarding leukemia as comparable to diabetes or pernicious anemia as mentioned in Dr. Murphy's paper, with regard either to its etiology or its treatment. Dr. Murphy has stressed an important point which has been too little appreciated, namely that patients should not be permitted to suffer relapses of their disease if that can be prevented. By carefully following the patient as a whole, his body weight, his general feeling of well being, the size of his spleen, his liver, his lymph nodes, his evidence of increased basal metabolism, leukocyte count, thrombocytes, erythrocytes and the degree and immaturity of his white cells, one can frequently forestall the relapse by appropriate treatment. This has long been the method of choice. I cannot agree with Dr. Murphy that the most striking effects of treatment with arsenic are to upset the patient. Solution of potassium arsenite (Fowler's solution), when given properly, almost without exception is a valuable therapeutic agent in chronic myelogenous leukemia. Solution of potassium arsenite must be given well diluted in fruit juice and must be given immediately after meals. The initial dose should be about 4 or 5 minims (0.25-0.3 cc.) three times daily, gradually increasing to an effective dose.

DR. H. J. ULLMANN, Santa Barbara, Calif.: As a radiation therapist it is gratifying to hear for the first time an internist say that one should control the radiation treatment of leukemia by the blood count and to treat with small doses rather than by massive doses the patient's symptoms. In lymphatic leukemia I depend more on the differential rather than on the total count because of the necessity for maintaining a sufficient number of polymorphonuclears to combat infection. In myelogenous leukemia the total count is of more importance with regard to reinstituting treatment, and frequently when the count is up, but there are no symptoms, such as an enlarged spleen or symptoms of discomfort, the judicious use of solution of potassium arsenite will carry the patient for months before further irradiation is needed. Many radiation therapists consider it wrong to give large or massive doses, and I feel that no dose should be given that makes the patient the least bit sick. I do not know whether general body irradiation is better than local, but I do know that in no instance should large doses be given. The basic dose that I use is from 50 to 100 roentgens measured on the skin, which is approximately 70 per cent of what is usually referred to in the literature as measured in air. The repetition of the dose, daily or otherwise, depends entirely on the blood count, which is made daily at first when the treatments are given daily, and, of course, the blood count must be made at the same time of day. No treatment is repeated until the count is known. I often find it difficult to get cooperation from an internist after the first course of irradiation because he turns to his textbook and if the count is not up to ten or fifteen thousand he does not refer the patient for either irradiation or consultation. The regulation of the dose and its timing should be in the hands of a radiation therapist, for if he is not a clinician he is not fit to treat with radiant energy. I do not think that, properly used, radiant energy is toxic in these cases. It can be used indefinitely if the doses are small enough. I have never seen thrombocytopenia caused by proper radiation therapy. If it did occur from such a cause I should consider that there had been gross overdosage. I did not know that any one believed one could produce an effect on the blood alone by irradiation. I have irradiated the blood in a rabbit's blood vessel, thoroughly isolated from the body, with enormous doses without producing any change in the cell count.

DR. WILLIAM P. MURPHY, Boston: Dr. Reznikoff asked with regard to my experience in respect to the development of anemia and thrombocytopenic purpura in the patients treated by means of small doses of x-rays applied by the "spray technic." There has been no greater tendency to the development of anemia in this group than in those patients receiving roentgen therapy in larger dosage over a more limited area. The erythrocyte and hemoglobin levels have in most instances been higher following treatment than they were preceding it; but this cannot

be interpreted too broadly because the development of anemia in the patient with leukemia varies greatly and is governed by factors not entirely dependent on x-ray exposure. Purpura has not developed following therapy in any of this group of patients. Severe and alarming leukopenia has developed in two or three patients treated in the hospital but not under my immediate observation. This condition is evidence of an overdosage of x-rays. If not extreme the leukocytes will gradually increase in numbers without specific therapy. If the leukopenia is severe, transfusions will usually keep the patient out of danger until regeneration occurs. One point which has been reemphasized and which applies in principle to the control of most chronic illnesses is that the best results will be obtained only with a careful and critical evaluation of the patient's entire blood and clinical picture throughout the period of illness.

HUMAN SERUM TRANSFUSIONS

CHICAGO

Moon¹ states that shock is "a circulatory deficiency, not cardiac or vasomotor in origin."

One of the fundamental requirements in combating shock is restoration and maintenance of adequate volume of the circulating blood. Whether shock is primary or secondary, whether due to hemorrhage, trauma or toxic substances, it is generally believed that there is a resultant diminished circulating blood volume and decreased peripheral blood flow. In the presence of dilated and more permeable capillaries, there is progressive blood stasis and subsequent loss of plasma into the tissue spaces. Thus the oxygen supply to the tissues is greatly curtailed. This course of events is progressive unless interrupted. One means of interrupting this sequence is to administer sufficient fluid to restore adequate circulating volume and improve the rate of blood flow. Furthermore, it is imperative that the vicious circle of progressively diminishing blood volume and blood flow and tissue anoxia should be interrupted as early as possible before severe and irreversible damage to the tissues occurs.

In the past, the most common fluids employed to combat shock have been crystalloid solutions such as dextrose, saline-dextrose and Ringer's solution. As was demonstrated in a series of experiments reported previously,² the crystalloid solutions are of only temporary beneficial effect. They increase blood volume but, owing to the fact that they do not remain in the circulation, their beneficial effects are only transient. When such crystalloid solutions diffuse out of the abnormally permeable capillaries the increasing edema is decidedly harmful. Acacia solution has been employed because this material remains in the circulation owing to its colloidal properties, but immediate and delayed reactions³ contraindicate its use.

and sustained the blood pressure until blood transfusions were started.

It must be pointed out that in these three instances any delay before treatment, even of only fifteen or thirty minutes, might have been fatal. Such delay is unavoidable with the use of whole blood. This is true even when an institution has a blood bank, because before preserved blood can be administered the patient's blood

fusion with a rise in blood pressure, slower and fuller pulse and improvement in the general condition.

CASE 4 (chart 3).—F. B., a secundigravida-secundipara aged 29, in the service of Dr. Julius Lackner, had had a classic cesarean section performed for complete abruptio placentae in 1936. On Feb. 20, 1940, a low cervical cesarean section was performed. After extraction of the baby 1 cc. of solution of posterior pituitary was injected into the myometrium in order

TABLE 2.—Summary of Results of Serum Transfusion in Other Conditions

Case	Age, Yrs.	Diagnosis	Indications for Serum	Laboratory Data	Amount of Serum	Response to Serum	Other Treatment	Comment
Shock (not associated with hemorrhage)								
17	44	Carcinoma of rectum	Resection of rectum; operative shock	Blood pressure fell from 130/86 to 50/40	500 cc.	Prompt; progressive rise in blood pressure	Intravenous fluids	Good operative recovery
18	23	Carcinoma of breast	Radical mastectomy; operative shock	500 cc.	Prompt; improved circulation	Good operative recovery
19	4	Congenital dislocation of hip	Open reduction; operative shock	Pulse and blood pressure imperceptible	250 cc.	Prompt; blood pressure rose to 85/55	Intravenous fluids	Delayed recovery; streptococcal septicemia
20	33	Multiple contusions, lacerations and fractured ankle following 45 foot fall	Traumatic shock	400 cc.	Prompt; recovery from shock	General	Uncomplicated recovery
21	21	Acute inversion of uterus	Visceral and operative shock	Blood pressure fell from 150/70 to 65/40	260 cc.	Gradual improvement	Stimulants; blood transfusion and fluids	Uncomplicated puerperium
22	36	Vaginal hysterectomy for menometrorrhagia	"Pituitrin shock" (1 cc. in myometrium)	Pulse and blood pressure imperceptible	400 cc.	Prompt improvement	Blood transfusion and dextrose intravenously	Uncomplicated recovery
23	29	Term pregnancy; previous classic cesarean section	"Pituitrin shock" (1 cc. in myometrium)	Pulse and blood pressure imperceptible	500 cc.	Prompt recovery, although improvement noted when serum started	Blood transfusion 4 days later	Uncomplicated recovery
Hypoproteinemias								
24	49	Starvation due to cardiopasm with nutritional edema and polyavitaminosis	Inadequate oral protein intake	Serum protein 3.8 Serum albumin 2.6 Serum globulin 1.2	110 cc. (4 × concentrated) 100 cc. (4 × concentrated)	Rise of serum proteins to 5.7 with diuresis and weight loss	Parenteral vitamin therapy; general supportive, antispasmodics	Gradual recovery
25	2½	Nephrosis	Low blood protein and marked albuminuria	500 cc. in 5 divided amounts	Questionable	Diuretics; general supportive	Improved
26	52	Acute and chronic hepatitis	Edema; low blood protein	Serum protein 5.5 Serum albumin 2.3 Serum globulin 3.2	1,500 cc. (divided doses over 2 weeks)	Temporary improvement	Blood transfusions; supportive, dextrose intravenously	Died; no reaction
27	43	(Idiopathic?) embolic occlusion of right iliac artery	Prolonged septic course; low serum protein and generalized edema	Serum protein 5.5 Serum albumin 2.6 Serum globulin 2.9	500 cc.	Increased urinary output and diminished edema	Amputation following embolectomy; 4 (500 cc.) blood transfusions	Eventual recovery
28	1½	Ruptured appendix and generalized peritonitis	Protein loss from draining wound	250 cc. (2 ×)	Cannot evaluate	Surgery; blood transfusions	Died 2 weeks postoperatively; no reaction
29	66	Gastro-enterostomy for old duodenal adhesions (postoperative)	Very low blood protein	Serum protein varied from 4 to 5.8	5,000 cc. (over 24 days)	Cannot evaluate	2,000 cc. blood (over 24 days)	Died; general peritonitis, bronchopneumonia; no reaction
30	2	Nephrosis	Low blood protein; albuminuria	Serum protein 4.3-4.8	Varying amounts of human serum; 4 × concentrated serum; human plasma	Increased urinary output; diminished edema	Diuretics, supportive	Response to whole serum equal to any other therapy; no response when febrile; no reaction
Burns								
31	5	2d-3d degree burns of 30 per cent of body surface	Plasma loss; shock	100 cc. (4 × concentrated) and repeated	Good	Blood transfusions; gentian silver nitrate spray to burn; fluids	Prolonged septic course; good recovery; no reactions
32	27	2d-3d degree burns of 75 per cent of body surface	Plasma loss; shock	100 cc. (4 × concentrated) 2 ×	Cannot evaluate	Tannic silver nitrate spray; two blood transfusions; fluids	Complicating bronchopneumonia; died; no reactions
33	17	2d-3d degree burns of 60 per cent of body surface	Plasma loss; shock	1,000 cc. many hours later	Cannot evaluate	Died within 24 hours; no serum reactions

must be typed and a compatibility test performed. Serum is kept on hand in the operating room and in the labor rooms, and no delay is encountered in its administration.

SHOCK NOT ASSOCIATED WITH HEMORRHAGE

The group of shock not associated with hemorrhage comprises seven cases, four associated with surgical procedures, two following the administration of solution of posterior pituitary injected into the myometrium during surgery and one due to trauma (table 2). In all instances the patients who had every clinical evidence of shock promptly responded to the serum trans-

fusion with a rise in blood pressure, slower and fuller pulse and improvement in the general condition. Within a few minutes the blood pressure and pulse became imperceptible. Two hundred and fifty cc. of physiologic solution of sodium chloride was administered, from which there was no apparent beneficial effect. Then 500 cc. of pooled human serum was injected. Following this the blood pressure was 102 systolic, 50 diastolic and the pulse 140 and of good quality. The blood pressure continued to rise and one hour later was 130 systolic, 90 diastolic. On the fourth postoperative day 500 cc. of citrated blood was given, following which a generalized urticaria developed. This was relieved by epinephrine. On the tenth postoperative day 0.1 cc. of dilute solution of posterior pituitary was injected intradermally; a marked erythematous pseudopodial reaction followed.

We are aware that most patients recover spontaneously from "pituitrin shock." However, it is a sound surgical principle to institute measures to combat shock when it develops from any cause. This case is particularly interesting since an allergic reaction to whole

Chart 3 (case 4).—Serum transfusion for shock following solution of posterior pituitary during cesarean section.

blood developed, whereas there was no reaction to the serum infusion.

These patients were not in as critical a condition as those in the hemorrhage and shock group, and it is probable that recovery would have occurred without serum transfusion. However, at the time these patients were in shock restorative measures were deemed necessary.

HYPOPROTEINEMIA

Seven patients received serum transfusions for the treatment of hypoproteinemia. In two cases this condition was associated with nephrosis in children, and the effects of serum transfusions were variable (table 2). In three instances hypoproteinemia was associated with septicemia, and serum transfusion apparently was beneficial although in two the course was ultimately fatal. In one instance the hypoproteinemia was associated with extensive damage of the liver and kidneys, and here likewise serum transfusion seemed of temporary benefit. Case 5, reported briefly, is of particular interest.

CASE 5 (chart 4).—P. DeV., a woman aged 49, in the service of Dr. I. I. Ritter, had suffered from "stomach trouble" for from fifteen to eighteen years. She had not sought medical advice and for the past two or three years had existed entirely on cream soup, broth, custard, jello and coca-cola. Examination and extensive study established the following diagnosis: cardio-spasm with esophageal dilatation; starvation with profound nutritional edema; polyavitaminosis, particularly B and C, and hypoproteinemia.

Treatment consisted of a high caloric diet, large amounts of vitamin preparations administered orally and parenterally, and antispasmodics. Oral protein intake was very limited owing to

the cardio-spasm, and the serum proteins remained low. Therefore 100 cc. of four times concentrated (lyophile) serum, equivalent to 400 cc. of normal serum, was administered twice for the hypoproteinemia. Chart 4 shows the curves of the blood protein values, urinary output and weight with this treatment. It is seen that following the second injection of concentrated serum the blood proteins rose markedly, and there was a concomitant diuresis and resultant loss of weight. This patient was discharged markedly improved.

BURNS

Three patients suffering from burns of the body were treated with serum transfusion (table 2). Two of the patients suffered very severe and extensive burns involving approximately 75 per cent of the body surface, and both patients died. The third patient, who was admitted to the hospital following severe burns of approximately 30 per cent of the body surface, received both serum and blood transfusions and ultimately recovered, despite a prolonged septic course resulting from infection of the burned areas.

We feel that serum transfusions will prove a valuable adjunct in the treatment of severe burns. Our experience is limited at present, but it is reasonable that the plasma loss and hemoconcentration can best be overcome by serum replacement therapy.

MISCELLANEOUS

Fourteen patients were treated for a variety of conditions: cachexia due to infection, hemorrhage and shock with purpura haemorrhagica, exfoliative dermatitis, pneumonia, acute catarrhal jaundice, generalized septicemia and chronic blood loss (table 3). No definite conclusions could be reached as to the value of serum transfusion in these cases because none of them were carefully studied and the serum transfusion was employed as a supportive measure. One case deserves more than passing mention:

A child aged 9 years with septic mastoiditis could be given no blood transfusion owing to universal incompatibility, possibly resulting from intensive sulfanilamide therapy.⁴ Serum trans-

Chart 4 (case 5).—Serum transfusion for hypoproteinemia.

fusion was employed as an alternative measure, although blood would have been preferable because of the profound anemia associated with the infection. However, the child was definitely benefited by the serum transfusion, and after the infection was controlled the patient made an uneventful recovery.

COMMENT

Serum transfusion as a blood substitute has been mentioned in the past.⁵ No practical use was made of this proposal until very recently. Brief reports⁶ have pointed out the merit of serum or plasma as a blood substitute. Our experience in the cases observed and reported in this paper completely confirms the evidence brought out in animal experiments⁷ that serum is an adequate blood substitute in shock. It appears that serum is an effective agent in many conditions in which blood transfusion would ordinarily be employed, with the exception of those conditions in which extensive loss of red blood cells occurs. Even in acute hemorrhage serum is a valuable temporary and intermediate treatment until blood can be secured, since it maintains circulating volume, thereby sustaining blood pressure and combating shock, anoxia and acidosis. The advantages of serum have previously been enumerated but can be summed up in the statement that serum can be prepared in very large amounts, can be stored over a long period of time without deteriorating and

sided subsequently. No reaction of a pyrogenic nature or blood group incompatibility was observed.

It is important to point out that the preparation of serum requires scrupulous care and meticulous technic. Many reports¹⁰ on serum prepared by trained personnel affirm the safety and innocuousness of this material. On the other hand, improperly prepared serum has been known to cause severe and even fatal reactions.¹¹

There are no great differences between plasma and serum as transfusion fluids. Essentially, freshly prepared plasma is serum plus fibrinogen, thrombin and one fifth dilution with 2.5 per cent sodium citrate solution. In our experience plasma cannot be kept over a long period of time because fibrinogen gradually precipitates out in the form of fibrin veils and granular precipitate and requires filtration or centrifugation and clearing before administration. After most or all of the fibrinogen has precipitated out, the solution consists essentially of serum diluted with sodium citrate. If the original intention of the laboratory is to prepare either serum or plasma, we believe that the former is prefer-

TABLE 3.—Summary of Miscellaneous Cases Treated by Serum Transfusions

Case	Age, Years	Clinical Diagnosis	Indication for Serum	Amount of Serum	Comment
34	10	Acute catarrhal hepatitis	General supportive regimen	250 cc.	Recovered
35	13	Banti's syndrome, pneumococemia, amebic dysentery	Generalized edema; ascites	500 cc.	Death; necropsy; Laënnec's cirrhosis
36	4	Influenzal meningitis	General supportive regimen	250 cc.	Death
37	9	Otogenic sepsis	Universal blood incompatibility	250 cc.	Progressive recovery
38	49	Streptococic lobar pneumonia	Nonspecific supportive therapy	500 cc.	Death
39	48	Severe exfoliative dermatitis (etiology ?)	Marked toxicity; cachexia	1,550 cc. in divided amounts over 2 mos.	Temporary improvement; died after 5 months
40	54	Ulcerative colitis	Cachexia; general supportive	250 cc.	
41	54	Gastric ulcer with obstruction; subtotal gastrectomy	Postoperative supportive treatment	500 cc.	
42	32	Thrombocytopenic purpura; intracranial hemorrhage	Moribund	700 cc.	tive day Death
43	47	Peptic ulcer with hemorrhage; heart failure	Elevated nonprotein nitrogen; cachexia	500 cc.	Temporary clinical improvement; subsequent death
44	?	Hypertensive encephalopathy	Inadequate protein intake	250 cc.	
45	58	Carcinoma of rectum; abdominoperineal resection	General supportive; cachexia	500 cc.	Extensive necrosis of abdominal wall; progressive recovery
46	4	Medulloblastoma of cerebellum	Cachexia	400 cc.	Death
47	42	Generalized peritonitis following ruptured appendix	Postoperative cachexia; blood transfusion reactions	2,000 cc. over 7 days	Improved; reaction to serum consisting of immediate pain, burning, swelling and redness along course of vein

can be shipped and handled easily. A factor of utmost importance is that serum transfusion can be given without preliminary typing and compatibility tests. The latter consideration has been discussed in a recent publication⁸ in which it is shown that agglutinin in the patient's serum absorbs infused agglutinins and inhibits their action on the patient's red blood cells. Furthermore, a low agglutinin titer serum can be prepared by pooling a large number of serums of varying blood groups.

Objection has been raised to the use of serum on the grounds that severe reactions are encountered.⁹ In the cases reported here, a reaction was observed in only one instance. This consisted of local pain along the course of the vein into which the serum was being injected, followed by redness and swelling which sub-

able because after its preparation and clarification by filtration it can be stored indefinitely, retaining its clear state. However, if a laboratory employs the plasma from outdated preserved blood, the supernatant plasma can be withdrawn and if not used within a short time it can subsequently be filtered to remove the fibrin precipitates and then stored for a long period of time. Adequate sterility tests must be performed whenever cloudy plasma is employed.

Flasks of serum are now being stored in labor rooms, operating rooms and first aid stations for immediate use in obstetric and surgical emergencies. The use of serum will increase the efficiency and adaptability of any hospital blood transfusion service, and outdated preserved blood need not be discarded. In the light of the foregoing discussion it is unnecessary to point out the great advantages of serum in the medical military service.

SUMMARY

1. Forty-seven patients suffering from a variety of conditions received human serum transfusions.

2. Patients suffering with shock from hemorrhage and other causes, hypoproteinemia or burns were definitely benefited by serum transfusion, and in a number of instances a dramatic recovery was observed.

3. The supply of serum is limited only by the supply of blood, and once it is prepared it can be preserved for a long time.

4. Serum transfusions may be given without preliminary laboratory typing and compatibility tests.

5. No reactions were observed or need be anticipated if serum is properly prepared. However, meticulous care must be taken in the preparation of serum.

6. Serum is preferred to plasma because it does not contain sodium citrate and because fibrin precipitates do not occur.

7. Serum is a valuable adjunct to any hospital or military transfusion service.

Twenty-Ninth Street and Ellis Avenue.

ABSTRACT OF DISCUSSION

DR. JOSEPH A. WAGNER, Bryn Mawr, Pa.: In our experience at the Bryn Mawr Hospital, reactions frequently follow the intravenous use of serum. Serum is the liquid phase of the blood separated after clotting has taken place, whereas plasma is the liquid phase of the blood separated without clotting. There are profound differences between the two substances which have been brought out in a number of ways. These may be grouped as follows: First, reactions following administration of fresh serum or serum preserved by drying from the frozen state. These have been reported in animals by Ravdin, Levinson and Freedman and their co-workers and in man by Aldrich, Ravdin and their co-workers and by Strumia and me. On the other hand, plasma fresh or preserved by either refrigeration or drying from the frozen state has now been widely employed by a number of experimenters in animals without reaction and clinically by Elliott, Lehman, Saint Girons, Ravdin, Knott, Edwards and others and by our own group. We have had experience with the material for at least eleven years, during which time more than 1,200 intravenous administrations have been given under closely controlled conditions and in doses as large as 2,000 cc. in twenty-four hours without disturbance. As much as 9 liters was given to one patient in eleven days. When one compares the electrophoretic pattern of serum and plasma as determined by the Titellus apparatus by Dr. Scudder, gross differences are at once appreciated. The cutaneous reactivity of animals and man to minute intradermal doses of serum and plasma offers a striking difference. When plasma is administered subcutaneously or intramuscularly, the rate of absorption is comparable to that of physiologic solution of sodium chloride. When serum is injected the rate of absorption is much slower. All these arguments point to a profound difference between serum and plasma and suggest, as Brodie first observed in 1900, that in the process of clotting a change is brought about in the serum which makes it toxic. Plasma has other advantages besides that of complete freedom from reaction. It is first of all more readily obtained than serum; second, it gives a greater yield of the liquid phase; finally, in the institutions where blood banks are established it is a readily obtained by-product. While we agree that on the whole physiologic effect of fresh serum is comparable to that of plasma in the treatment of shock, the fact that plasma has mechanical advantages in separation and freedom from reactions when administered intravenously makes it the material of choice.

DR. SIDNEY O. LEVINSON, Chicago: It is surprising that the discussion does not involve the validity of the claim that human serum is a good substitute but rather focuses around the question of whether serum or plasma is superior. Such controversy appears relatively unimportant, because both answer the purpose of supplying a human colloid protein-containing fluid. I hold no brief for either serum or plasma. Where the latter is more

easily available and prepared (as in blood banks), plasma should be used; where the former can be properly and easily handled, serum is to be preferred. I protest emphatically that properly prepared serum is not toxic. Human serum has been used extensively in Illinois by thousands of physicians in the last ten years, and with the exception of occasional allergic reactions no ill effect has been experienced or reported. Toxic reactions, such as those reported by Dr. Strumia, have been conspicuous by their absence. The handling of clotted blood is different from that of citrated blood. The unfavorable laboratory and clinical results reported may well be due to the use of technic different from that employed successfully by the various serum centers throughout the country. Wide experience from all serum centers indicates that properly prepared serum is safe. I have no doubt that if plasma was improperly prepared it would not be innocuous. We are all aware of the fact that even a simple material like saline solution may cause severe reactions. Technic and care in preparation are of the greatest importance. In all other matters I agree with Dr. Wagner. Either serum or plasma, having the same essential properties, may be used to great advantage and with complete safety.

REDUCTION OF ELEVATED BLOOD
PRESSURE BY ADMINISTRATION
OF RENAL EXTRACTS

ARTHUR GROLLMAN, M.D., PH.D.

BALTIMORE

J. R. WILLIAMS JR., M.D.

AND

T. R. HARRISON, M.D.

NASHVILLE, TENN.

A number of investigators have claimed beneficial results from the administration of renal extract. The earliest studies were those of Brown-Séquard and d'Arsonval¹ in 1892 and of Meyer² the following year. These authors reported that nephrectomized animals were improved by their crude extracts. More recently it has been stated³ that renal venous blood contains a substance which in animals causes diuresis, with reduction in the amount of sodium, chloride, potassium and urea in the blood. It has likewise been claimed⁴ that extracts of the kidney cause diuresis and reduction of blood pressure in patients with nephritis. These therapeutic claims have not been confirmed nor have they received any serious consideration by competent authorities for a number of reasons. In the first place the hypotensive action claimed for these extracts has not been demonstrated in hypertensive animals. Secondly, the clinical data have not been convincing. In most instances only one measurement of blood pressure has been reported prior to the administration of the renal extract. Since it is well known that striking variations in blood pressure occur in hypertensive subjects and since it is generally recognized that such patients usually have a higher blood pressure when first observed by a physician than when subsequently seen by the same

This work was aided by grants from the Josiah Macy Jr. Foundation and from Mr. Joe Werthan.

A preliminary account of the work was reported before the American Society for Clinical Investigation, May 1, 1939.

occurred in most of the experiments.²¹ The fact that in an occasional dog no reduction of blood pressure was observed was readily accounted for when the quantity of the active principle administered as determined by assays on rats was taken into account. It was found that from thirty to fifty times as much material had to be given to dogs in order to induce the same decline in blood pressure as occurred in rats. In the initial stages of our work it was difficult to produce sufficient of the extract to treat such a large animal as the dog, and it was often difficult to persuade the animal to ingest it. Vomiting occurred frequently after the administration of the preparation by stomach tube. In the dog as in the rat, toxic effects were frequently observed. These appeared to be of two types. In some animals no untoward effect appeared following a reduction of from 20 to 40 mm. in blood pressure. However, in other animals, and especially in those with marked hypertension of long duration, a drastic decline in blood pressure was accompanied by manifestations of uremia and even by death. In a third group of dogs, which were given relatively small amounts of the active principle as determined by assays on rats, untoward effects occurred without any decline in blood pressure. These effects, which were evidently due to the impurities in the extract, consisted in vomiting, weakness and usually diarrhea. More detailed discussion of the effects of these renal extracts in hypertensive animals have been published elsewhere.²²

The foregoing discussion concerning the effects of renal extracts on the blood pressure of hypertensive animals may be summarized by saying that it seems to be established beyond question that animals with experimental renal hypertension respond to such extracts with a decline in blood pressure. However, the question as to whether such a decline is in fact desirable or undesirable has not yet been clearly proved.

Chart 5.—Oral administration of renal extract was attended by a well marked decline in blood pressure, the effect being of short duration, lasting only for two or three days. On a later date a small dose of renal extract was administered intravenously and a decline of blood pressure of about 30 mm., lasting for about three days, occurred.

For this reason, attempts to treat human beings have naturally had to be carried out slowly and with the greatest caution.

OBSERVATIONS CONCERNING EFFECTS OF ADMINISTRATION OF RENAL ANTIPRESSOR SUBSTANCE TO PATIENTS WITH HYPERTENSION.

Thus far our observations on patients have been limited to subjects with advanced and severe hypertension. The first patients treated were given amounts of extract which we now know to have been far too

Chart 6.—This illustrates the immediate effects of the intravenous administration of renal extract. The marked decline in blood pressure which came on about two hours after the injection and was followed by a chill possibly represented a nonspecific protein reaction. The more lasting moderate decline was possibly due to the specific effect of the renal extract.

small to have any marked effect. We have treated only a few patients with an amount which would seem adequate, as judged by assays on rats, namely 150 or more oral units a day for a period of several days. The first patient to receive the extract orally in adequate amount was treated in November 1938. This man had malignant hypertension with beginning uremia. He had chronic prostatitis with urinary retention and was therefore catheterized throughout the course of treatment. Because he was desperately ill, the extract was begun on his third day in the hospital. The blood pressure was measured at intervals of every four hours, all of the measurements for a given day being averaged and recorded as one point in chart 3. After several days' treatment a marked decline in blood pressure occurred. About the same time definite clinical improvement with decline in the nonprotein nitrogen of the blood was observed. However, the latter effects may well have been due to the effects of catheterization. As soon as the blood pressure displayed a well marked decline, the treatment was stopped. The blood pressure remained at a relatively low level for several days and then rose to the preexisting value, the patient's symptoms becoming worse. Shortly afterward pneumonia developed and the patient died.

The second patient given adequate amounts of the extract was treated in April 1939. In this case the level of the blood pressure had been studied carefully for a period of several weeks in the hospital a number of months before. After an additional admission to the hospital and a week's control period the administration of the extract was begun with apparently gratifying results on the blood pressure and on the headaches.

21. Williams, J. R., Jr.; Grollman, Arthur, and Harrison, T. R.: *Am. J. Physiol.*, to be published.

22. Harrison, Grollman and Williams.¹⁸ Williams, Grollman and Harrison.²¹

After several weeks the blood pressure had gradually risen to the pretreatment level and the extract was again administered orally with an apparent decline in pressure (chart 4).

Results on another patient are illustrated in charts 5 and 6. This patient was given a total of about 200 rat units in forty-eight hours. The extracts then had to be discontinued because of diarrhea, which was accompanied by some nausea and vomiting. These symptoms were due we believe to impurities in the extract. This patient exhibited a well marked decline in blood pressure, which lasted, however, for only about twenty-four hours, the pressure then returning to the preexisting level. In order to determine whether the decline in blood pressure could be accounted for solely on the basis of the diarrhea, the patient was later given an amount of magnesium sulfate sufficient to produce a diarrhea approximately as severe as that which occurred during the administration of renal extract. No significant decline in blood pressure occurred. This patient was later given additional renal extract intravenously and a second decline in blood pressure occurred. The possibility that this may have been due to a nonspecific protein reaction has not been eliminated.

In one patient treated orally no decrease in blood pressure was observed even though the patient received what appeared to be adequate amounts of extract during a period of several days. The blood pressure curve of this patient is shown in chart 7.

Observations made during August 1939 on a fifth patient are illustrated in chart 8. This man had severe and advanced malignant hypertension. Prior to the administration of renal extract he was in a state of stupor, was disoriented and had severe headaches which had failed to respond to the usual methods of treatment. During the administration of the renal extract a slow decline in the blood pressure occurred, and this persisted for a number of days after the therapy was discontinued. Coincident with the decline in blood pressure there was marked improvement in the mental

decline which occurred during and immediately after the administration of renal extract. Results similar to those here reported have been obtained in several other patients. These will be reported in detail at a later date. Although all of the patients who have been cited were studied while in the

Chart 8.—This patient was given large doses of the extract by mouth for a period of two days, followed by small doses for ten days. During this period there was a moderate decline in blood pressure and well marked clinical improvement. After the extract had been discontinued the blood pressure rose slowly over a period of ten days to the previous level. At a later date he showed a spontaneous decline in blood pressure, which was less striking and of shorter duration than that which occurred while he was receiving the extract. Symptomatic improvement was marked in this man during the time the extract was being given.

Chart 7.—Although this patient received moderate sized doses of renal extract by mouth over a period of two weeks, no significant decline in blood pressure occurred.

hospital and although with the exception of the first patient the blood pressure had been observed for a considerable time before the administration of renal extract, we prefer to draw no conclusions as regards the therapeutic effect in patients. The subjective improvement which seemed to occur might conceivably have been the effect of suggestion. Although the method of study makes it very unlikely that the declines in pressure could have been spontaneous, this possibility has not been entirely excluded. Extremely large amounts of kidney are required at the present time in order to produce a single human dose. Furthermore, there is at present no certain method of determining which patients have hypertension of renal origin, and it is only on such patients that the extract would be expected to be effective. Finally, since a marked decline in blood pressure occurring after the administration of the extract in animals has frequently been associated with severe untoward symptoms, great caution must necessarily be used in the treatment of patients until more is known of the nature of this reaction. Every effort is being made to overcome these difficulties as rapidly as possible. The fact that Page, Helmer, Kohlstaedt, Fouts, Kempf and Corcoran²³ have subsequently but independently obtained both in animals and in patients results comparable to those here recorded, which confirm our earlier reported work,²⁴

23. Page, Irvine; Helmer, O. M.; Kohlstaedt, K. G.; Fouts, P. J.; Kempf, G. F., and Corcoran, A. C.. Personal communication to the authors.
24. Our results demonstrating decline in blood pressure in hypertensive animals and patients following the administration of renal extract were reported before the American Society for Clinical Investigation, May 1, 1939; before the Cleveland Academy of Medicine, September 15; before the Johns Hopkins Medical Society, November 13; before the Washington Heart Association, November 15, and before the American Association for the Advancement of Science, December 29.

strengthens the probability that the declines in blood pressure exhibited by our patients have been due to the therapy rather than coincidental. However, until the difficulties mentioned can be overcome and until a much larger series of patients can be studied, we prefer to regard the studies on patients as inconclusive and as still in the experimental stage.

The chemical nature of the active principle of our extract is still uncertain. Under proper conditions of temperature, salt concentration and pH the active principle is soluble in 40 per cent acetone and can be precipitated by the addition of further acetone in sufficient quantity. It can also be precipitated by the use of ammonium sulfate or by saturation with sodium chloride. Details concerning the method of preparation of the crude extract have been published elsewhere.²⁵

animals. So far as we know, no other substance has been described which has the properties of long duration of action, effectiveness by mouth and lack of reduction of blood pressure in normal animals as compared to marked reduction of blood pressure in animals with renal hypertension. As far as we can judge from the available data, the extracts derived by other investigators from tissues other than kidney display few properties in common with our preparation. More comprehensive investigations concerning the chemical and biologic properties of the active substance are in progress and will be reported on at a later date.

SUMMARY

1. Recent experimental studies indicate clearly that a rational and logical basis exists for the possible therapeutic value of renal extract in hypertension of renal origin.

Comparison of Some Properties of the Renal Antipressor Substance with Those of Certain Depressor Substances

Substance	Source	Hypotensive Effect on Experimental Animals				Oral Effectiveness Demonstrated	Precipitation by Ammonium Sulfate	Dialyzability	Comment
		Normal Animals		Hypertensive Animals					
		Decline	Duration	Decline	Duration				
Histamine.....	Nearly all tissues	+	Seconds or minutes	+	Seconds or minutes	0	0	+	No depressor effect in etherized rabbits
Acetylcholine.....	Many tissues	+	Seconds or minutes	+	Seconds or minutes	0	0	+	Depressor effect abolished by atropine
Adenosine (and related compounds)	Muscle, blood (all tissues)	+	Seconds or minutes	+	Seconds or minutes	0	0	+	Causes heart block in guinea pigs
Urohypotensin (Abelous and Bardier)	Urine	+	Minutes	?	?	0	+	0	Constriction of pupil of rabbit's eyes (?)

RELATION OF RENAL ANTIPRESSOR SUBSTANCE
TO OTHER PREVIOUSLY DESCRIBED TISSUE
EXTRACTIVES

The renal antipressor substance described in this paper differs in many respects from the depressor preparations reported by others. The table presents a summary of certain simple chemical and pharmacologic properties of the extract as compared with certain non-specific depressor substances of known chemical composition and as compared with extracts described by previous investigators. The chemical properties and the type of action are entirely different from those of histamine, choline and the adenosine group of compounds. There likewise appear to be distinct differences from the products obtained by others from kidney, and although our extract has certain properties resembling those of urohypotensin and depressan it differs from these in that oral doses which cause marked decline in the blood pressure of animals with renal hypertension have little or no effect on the blood pressure of normal

2. Extracts of the kidney have been prepared which, when administered orally to normal animals, do not produce a decline in blood pressure but have the property of partially inhibiting the pressor effect of subsequently injected renin.

3. When extracts containing the renal antipressor substance in sufficient amount are administered, either parenterally or orally, to animals with experimental renal hypertension, a well marked and prolonged decline in the blood pressure occurs.

4. A small number of patients have been treated by means of the oral or parenteral administration of the renal antipressor substance. In most of the subjects a decline in the blood pressure has occurred. However, for reasons which have been mentioned we prefer not to draw any conclusions at the present time from these observations.

5. The available evidence indicates that the renal antipressor substance has certain unique properties which differentiate it from various depressor tissue extractives described by previous investigators.

710 North Washington Street.

ABSTRACT OF DISCUSSION

DR. MURRAY STEELE, New York: Dr. Harrison has been largely instrumental in bringing before us in this country the work of Tigerstedt and Bergman, which was confirmed and extended by Bigel and Strauss and by Hessel and Hartwich. Shortly after he had become interested in the pressor substances, observations of the behavior of reactions of animals led him to the deduction that there was an antipressor substance also in the renal tissue. From this point on he was fortunate in being associated with Dr. Grollman, and they have this morning presented the results of that work. I should like to point out a phenomenon which is of extraordinary interest in the development of these researches. When interest in a subject is great, many laboratories soon become involved. Since we can in these days disseminate news more rapidly by publication and at meetings, the frequency of simultaneous work and simultaneous discoveries increases and I think this work is an example of that fact. By entirely different reasoning, in two separate laboratories, the same conclusion has been reached at almost the same time. Dr. Harrison, from intimate knowledge of the behavior of animals injected with renin and from the knowledge that removal of the kidneys will increase the rise in pressure obtained with renin, deduced that there was an antipressor substance in the kidney. Dr. Page, in his laboratory, from more purely chemical reasoning, from the fact that in a perfused animal something in the blood was used up which was not the renin activator, yet which prevented the action of the renin-renin activator system, came to the conclusion that a renal antipressor substance developed. Dr. Harrison has emphasized the fact that this depressor substance is costly, very difficult to obtain at the moment, and that it is not yet clear what the clinical uses are or will be. What is clear is that a most extraordinary tool for the further study of the mechanism of the development of renal humoral hypertension has been found.

DR. M. C. WINTERNITZ, New Haven, Conn.: The procedures that have been utilized are valuable in association with humoral pressor effects elicited through the kidney. As a pathologist, my interest lies in structural variants of disease and not in physiologic or chemical detail. During the past year these approaches have been found indispensable. The authors have said everything I might have contributed in discussion and they have been conservative. They have raised the question whether it is desirable to lower blood pressure in renal hypertension. Now that we know hyperpyrexia is of therapeutic value in some diseases and no longer always want to reduce fever, perhaps a similar point of view may be desirable for hypertension. "Renin" is a crude product; its fractions have not been isolated and consequently their chemical and physiologic properties are not known. The ammonium sulfate preparation which the authors mentioned contains pressor and depressor substances as well as agents that necrotize muscle, including heart muscle and the smooth muscle of arteries, veins and other hollow muscular viscera, also diaphragmatic muscle but not skeletal muscle. It probably contains still other factors that result in hemorrhages. The fate of individual substances of such a group when given by mouth is in itself a problem. A similar preparation injected intravenously into dogs with or without kidneys results in vascular lesions of the type that characterize malignant nephrosclerosis. Renin D, I think our chairman has prepared. It has been purified by Dr. Swingle, and my associate Dr. Mylon has carried the separation further. Renin D contains three ferments for which it has been tested and perhaps many more. The three are a tryptic, a peptic and a catalytic type. It also has a high protein content and its nonprotein nitrogen will increase rapidly at body temperature. The enzyme activity and almost all if not all of the protein of renin D are removable. At this stage, when the nitrogen is reduced to 1 microgram for every kilogram of the dog's weight, intravenous injection results in a typical renin elevation of the blood pressure of from 50 to 75 mm. of mercury. Even this product can be shown to be impure by bio-assay. Obviously intravenous use of renin is fraught with danger. Experimentally it has great value for the production of malignant nephrosclerosis with lesions in many important viscera including the myocardium, brain, kidneys and blood vessels. There is no doubt great dif-

ference between its administration by mouth and intravenously. Nothing that I have said, therefore, could apply to its use by the first method.

DR. EDGAR ALLEN, Rochester, Minn.: The work which Dr. Harrison and his associates and others are doing is of great interest to those who practice clinical medicine. Many patients with so-called essential hypertension or hypertension of other origins are seen and physicians are desperate for some remedy to take care of these patients. In present day American life essential hypertension seems to be the most serious disease, accounting for at least twice as many deaths as cancer. It would not be fair to leave this discussion on the note that it is not desirable to lower blood pressure in essential hypertension. I am sure that what Dr. Harrison meant to discuss and what Dr. Winternitz wished to emphasize was that it may not be desirable to reduce blood pressure by means of the extract which Dr. Harrison has discussed. However, it is highly desirable to lower the blood pressure of patients with essential hypertension, and when this is accomplished all the serious effects of hypertension disappear. The work which began with Dr. Goldblatt and has been carried on by Dr. Harrison and his associates and others has been of great interest to experimental medicine. It does not detract from this work to say that with minor exceptions it has not been of any help to clinicians who take care of patients with essential hypertension. The single exception to date is that occasionally one sees a patient with hypertension which is indistinguishable from the so-called essential hypertension in man, which is renal in origin and which has been cured by the removal of a diseased kidney. There are in the literature at least 100 remedies for essential hypertension, and the conservative way in which Dr. Harrison has approached this problem precludes the possibility that there would be unjust claims by him or his associates. However, if the usual program follows, there will be unjustified claims by others. The implication has been that, since this extract reduces the blood pressure of animals with experimental hypertension and does not reduce the blood pressure of animals with normal blood pressure, it has a specific effect on the genesis of hypertension induced experimentally. However, it is easy to reduce the blood pressure of many patients with essential hypertension and quite difficult to reduce the blood pressure of patients with normal pressure. Sleep may reduce the blood pressure of a patient with hypertension from, say, 240 systolic to 160 systolic, or 140 systolic, but sleep will not reduce the blood pressure of a patient with normal blood pressure more than 10 or 15 mm. of mercury. It would not be fair to conclude from this observation that the reason the patient with essential hypertension has elevated blood pressure is that he has not had sleep. It is true only that it is easier to reduce the blood pressure when it is elevated than when it is normal.

DR. FREDERICK M. ALLEN, New York: The problem of renal-vascular disease is so complex that a coordinated approach is apt to be most productive, as I believe was illustrated by our investigation which began in Morristown in 1920, following the same lines as had previously been pursued in diabetes. For historical interest, and in behalf of about a dozen former co-workers, I wish to mention the following published results: 1. Extensive studies with partial nephrectomy furnished the first demonstration that the principal phenomena of nephritis are explainable by simple quantitative reduction of functioning renal tissue. 2. Explantation of the kidneys was devised for various investigative purposes, which could only partly be carried out. 3. With the aid of a new auscultatory device for routine pressure readings in dogs, the first discovery of experimental chronic hypertension was made by clamping the kidney blood vessels, a method which not only holds priority but which also can be shown to be still the best hypertensive method for some purposes. 4. Therapeutically, rigid exclusion of salt from the diet was proposed. Here disputes can confidently be left to ultimate decision on one single unavoidable issue, namely accuracy of clinical observation. 5. No study was made of Tigerstedt's hypertensive substance renin, but an attempt in the direction of organotherapy yielded the first discovery of an acid-alcohol extract of fresh kidneys which was able to reduce blood pressure. In view of the recent activities along all five of these lines, it is worth noticing that all these developments would have been equally possible fifteen years ago. The delay has been

due solely to the power of a monopolistic autocracy not only in controlling but in suppressing research. There were also other fundamental lines of investigation, besides the five mentioned, which were not published and have not been discovered elsewhere; and no lack of effort on my part has been responsible for stopping both this and my diabetic work. The kidney extract research would have been lost altogether if it had not been continued by Dr. Jablons. He seems to have a priority of several years in some methods of purifying the extract and in studies of sodium and potassium, which may explain some of the variable or fatal results described by others. I have not been able to keep in touch with details of the recent developments in this field, which are both brilliant and confusing. Dr. Harrison and his collaborators are to be congratulated on their reported success with oral administration, and the papers by other authors have combined to make this one of the subjects of leading interest in this convention. Nevertheless, I revert to my original statement concerning the complex renal-vascular problem. Kidney extract does not furnish the entire solution of this problem. However great its theoretical or practical importance may prove to be, I think most investigators will join in warning practitioners that no spectacular remedy like insulin is at hand. We may be on the way, but we have not yet reached any certainty regarding either the cause or the cure of essential hypertension.

DR. BENJAMIN JABLONS, New York: Dr. Harrison's report is heartening to those of us who have been active in this field for some time. I have been working with kidney extracts for nine years. During that time two outstanding facts have become apparent, and the work of Dr. Harrison, Dr. Page and others confirms them. The first is that the hypotensive extract is not easily obtained. While a laboratory extract will give very startling results used on patients or in experimentally induced hypertensive animals, the same material produced on a large scale in a pharmaceutical plant will often not give the same results. The second is that suitable cases must be selected. In analyzing failures I have found that it was important to make certain that the individual for whom this extract is to be used does not have irreversible changes in the arterioles. Recently I have tested a number of these cases for the presence of peripheral vasospasm and have found it in a considerable number of cases of essential hypertension. If kidney extract produces peripheral vasodilatation, one is encouraged to proceed with its use and can expect satisfactory results. Another reason which I believe contributed to failure in some instances was the presence of protein in the extract. For eight years I have been working with a protein-free extract. With this protein-free, aqueous acid-alcohol extract I have obtained some very startling results. I have also had a number of failures. We are indebted to Dr. Harrison and his co-workers for emphasizing the oral use of extract. A few years ago I used it orally without results. Encouraged by his published results, I have again used our extract orally in seven cases. Four responded, two failed, and in one case the condition was definitely aggravated. Our extract is not toxic to animals in doses below 6 per cent of body weight. It is prepared by a method presented before the New York State Medical Society in May 1937 and published in the Jan. 1, 1938, issue of the *New York State Journal of Medicine*. One case of malignant hypertension has been under treatment since May 1933, and many others of shorter duration have shown no toxic effects. By watching the blood electrolyte concentration and chloride excretion in the urine, one can determine indications and contraindications for extract administration. The summarized results will be published shortly.

DR. T. R. HARRISON, Nashville Tenn.: I agree with Dr. Winternitz that an ammonium sulfate precipitate has in it many things, and it is because of this fact that we have mainly employed oral administration even though larger amounts are needed. We are hoping that the time will soon come when we may be able to purify the material better and shift over to parenteral therapy. As to whether it is desirable to lower the blood pressure, I think it is but am not certain. The question is, Is it desirable to lower it to normal, assuming one could? That I don't know, and certainly some of our animals have died when the pressure has been lowered to normal. We aren't certain that the lowering of blood pressure has been the cause of death. It may have been due to some impurities in the

extract. But until we get over that hurdle we have to be extremely cautious. About the specificity, our own evidence suggests that the material is specific for kidney but more studies are necessary before we can be certain. The difficult question as to whether essential hypertension is renal I am going to dodge by saying that in my own opinion, which is subject to revision at any moment, some instances are and some are not. I should like to point out to Dr. Jablons that there have been no deaths of patients in Nashville, and Dr. Page tells me none in Indianapolis. Because of the deaths of animals one has been cautious about administering this to human beings. I think that if some of the previous workers had studied hypertensive animals before they studied hypertensive patients their problems might have progressed more rapidly. This isn't confirmation of Dr. Jablons' work. Dr. Jablons reported that with a fraction obtained by extraction of kidney in about 95 per cent acid alcohol he could obtain an active blood pressure lowering substance. One of the methods we frequently use to make our material is to collect it in 95 per cent acid alcohol, but we throw away the material that is soluble in 95 per cent acid alcohol, which is what Dr. Jablons uses; and the material that is insoluble, which Dr. Jablons discards, gives us the typical results, so that it is quite clear that Dr. Jablons is dealing with one kidney extract and we are dealing with another, and that they are not the same thing. Which is the better kidney extract, time will have to tell.

OSTEOMYELITIS OF THE SKULL FOLLOWING FRONTAL SINUSITIS

A. S. MACMILLAN, M.D.

BOSTON

Before considering osteomyelitis as a complication of frontal sinusitis it might be well for me to review briefly the roentgenologic aspects of the acute and chronic infections in this area which have traveled up the frontonasal duct.

Before one can arrive at an intelligent interpretation of the density of a sinus as seen in the postero-anterior view, one must examine the lateral view for the depth of the sinus and for the thickness of the anterior and posterior walls and note any irregularities in both depth and thickness. One must then note the character of the bones of the skull—the relative thickness of the cortex to that of the medulla. Then, and only then, can the density one expects to find in the frontal view be evaluated.

The minimum number of views that should be taken are four, namely a lateral, a postero-anterior, a Waters position in the prone and a fluid level position.

When the nasofrontal duct becomes completely or partially blocked, the membrane thickened and its secretion retained within the sinus, it is always surprising how little increase there is in density over the normal. Often the difference in density between the two frontal sinuses is so slight, even when they are completely filled, that other means of diagnosis must be looked for. In this connection it must be remembered that normally there may be an opening in the bony septum between the two frontals, and when this occurs the membrane of the normal sinus becomes thickened and pushed away from the interfrontal septum.

It is a well established fact that acute inflammation of the mucous membrane causes decalcification of the underlying bone. This is as true in acute frontal sinusitis as it is in mastoiditis. One change I look for in mastoiditis is decalcification of the mastoid cell

Read before the joint meeting of the Section on Laryngology, Otology and Rhinology and the Section on Radiology at the Ninety-First Annual Session of the American Medical Association, New York, June 14, 1940.

partitions. I expect this to occur in from seven to ten days after onset of infection of the mucous membrane. In frontal sinusitis one must watch for this decalcification. Loss of the entire outline of the sinus due to this loss of the inner cortical lining is to be

Fig. 1.—A white youth aged 16 had a history of sinusitis with swelling about the left eye three weeks before admission. This subsided. Two days before admission swelling of the left eyelids recurred and there was swelling about 2 cm. in diameter in the midline above the frontal sinus. A roentgenogram revealed an area of osteomyelitis at this point. Removal of a wide area of bone including the necrotic area resulted in recovery without complications.

expected, but localized loss of the outline is an entirely different matter.

In subacute and chronic sinusitis, lasting a matter of weeks, there is an increase in density of the anterior and posterior walls and the surrounding bone, nature's walling off process. This eventually results in sclerosis so consistently seen in these chronic infections. At

Fig. 2.—A white girl aged 16 years had a history of infection of the upper respiratory tract and frontal headache fifteen days before admission. Four days later she had swelling and edema of the forehead—development of an orbital abscess—which was drained with complete subsidence of all symptoms. Nine days later severe frontal headache, nausea and vomiting occurred. Examination revealed evidence of a brain abscess of the left frontal lobe. This was drained. The sinuses at this time were perfectly clear. One month later, with no intervening symptoms, edema and tenderness developed over the left eye. X-ray examination disclosed osteomyelitis of the front wall of the frontal sinus extending out into the frontal bone; radical removal of the bone was done and recovery was uneventful.

times it is difficult to make out fluid levels through this sclerosis, again showing how small a part the density of the contents of the sinus has to do with the total density.

The progress of infection of an acute frontal sinus, which must be watched for, is the change in density, loss of its outline and the reaction in the surrounding bone. In a case of severe acute infection in which frontal headache is accompanied by swelling and edema of the tissues over the outline of the sinus, but sharply limited to the area of the infected sinus, a constant watch should be maintained for minute perforations of the anterior wall. These perforations are caused by the enlargement of the thrombosed small penetrating vessels coming through the bone from the infected mucous membrane. These minute perforations can be detected in the anterior views and are one of the early x-ray signs of bone infection. Localized loss of the outline due to actual necrosis of the wall at one point is an important accompanying finding. A tangential view of the frontal wall in question may show localized necrosis. Infection must be present at least a week before these signs become evident.

Involvement of the posterior wall of the frontal sinus may be determined by noting the change in the

Fig. 3.—A white man aged 25 had left pansinusitis with an orbital abscess. An external frontal operation (Lynch) was done; ten days later there were signs of an intracranial pathologic condition. He was referred to the Massachusetts Eye and Ear Infirmary. Examination revealed osteomyelitis extending by thrombophlebitis from the outer border of the left frontal sinus. At operation a large extradural abscess was found. Recovery resulted.

pattern of the composite picture of the anterior and posterior walls, as seen in another view. If the infection remained in the mucous membrane, or even in the bone, conditions would not be so serious.

The thrombosed vessels of the mucous membrane which carry infection into the bone are continuous with those entering the dura and brain, and blood sinuses, and may produce infection in these areas. These serious complications may occur simultaneously with the bone infection so that an apparently solid posterior wall of an infected frontal sinus may be covering an extradural or brain abscess.

The frontal bone is rich in diploetic veins. Two fairly constant plexuses occur at the outer angles in the region of the frontal bossae. Others may be seen to course through the walls of the frontal bone and enter blood lakes or parasinoidal sinuses, which in turn empty into the longitudinal sinus. For the many veins large enough to be seen on the x-ray films there are

also many microscopic ones that are as important in the process of dissemination of the infection. These blood vessels and sinuses should be watched for either any change in their outline or any loss of density in the surrounding bone. This involvement in the diploe is

Fig. 4.—A Negro aged 19 years had left frontal sinusitis with extension of infection into the left frontal bone; operation consisted of removal of the infected bone and some normal bone, working from the infected area outward. This conservative operation was followed by further extension and the development of a brain abscess from which the patient died. Osteomyelitis of the skull cannot be dealt with in a conservative manner.

very rapid, and change can be detected from day to day on the x-ray film.

My experience with the x-ray appearances in infection of the frontal bone, secondary to frontal sinusitis, extends over a period of twenty years, during which time I have seen a marked change in treatment of osteomyelitis. In the eighty-six cases which I have seen at the Massachusetts Eye and Ear Infirmary, the infection was limited to the front or posterior wall of the sinus. The mortality in the group was 14 per cent, deaths being due to epidural abscess, subdural abscess, brain abscess or meningitis. Thirty-six patients developed osteomyelitis extending beyond the limits of the frontal sinus into the frontal bone (figs. 1, 2 and 3).

Fig. 5.—Reproduction of a roentgenogram of a removed fragment of frontal bone measuring 10 by 5 cm., showing in the lower part the outline of the frontal sinuses and above the osteomyelitis breaking out along the thrombosed diploetic veins. Microscopic examination of the decalcified bone showed marked involvement in the areas that appeared normal by x-ray examination.

the surgeon usually waited for x-ray signs of osteomyelitis. When the diagnosis was made by the roentgenologist, the necrotic bone and some of the normal bone were removed. It was not fully realized that the bone

would be infected for from $1\frac{3}{4}$ to 2 inches beyond the necrotic area discernible on the x-ray film. If the surgeon wished to be conservative he waited, hoping that the lesion would localize and that sequestrums would form which he could remove. The tragedy of this method was that in every case in which sequestration was awaited a fatal complication arose.

During the time when the delayed or incomplete type of operation was in use frequent x-ray examinations were made to see whether any further involvement was taking place. The mortality rate with this type of puttering surgery was high, 58 per cent (fig. 4).

In the last seventeen cases a large part of the frontal bone was removed in one operation, including the infected area, and out into healthy bone for upward of 2 inches, thus eliminating osteomyelitis, the cause of the complications (figs. 5 and 6).

In the fulminating cases operation was done before any indication of involvement could be seen by x-ray examinations for the diagnosis depended entirely on the one all important sign of pitting edema. Microscopically the removed bone has always been found to

Fig. 6.—Appearance eighteen months after radical removal of part of the frontal bone for extensive osteomyelitis. This also shows the first bone graft put in by the plastic surgeon to cover the defect.

be thrombosed with infected veins; in a number of these cases x-ray examination of the specimen showed nothing to suggest the diagnosis. This form of treatment has reduced the mortality to 25 per cent, and if the two cases in which operation was done in the presence of an overwhelming fulminating meningitis are eliminated from this count, the mortality would be down to 12.5 per cent. The meningitis in these cases arose from an infection of the upper respiratory tract of from four to five days' duration. There was pus in the frontal sinus and pus oozing from the cut surface of the bone even at the hair line. In such cases the operation could be regarded only as a gesture.

CONCLUSION

1. Osteomyelitis of the skull, because of its complications, is a most serious disease.
2. The x-ray evidence of this disease should not be waited for in the presence of clinical evidence.
3. Pitting edema to the hair line is a positive sign of infected bone.
4. Puttering surgery invites disaster.

483 Beacon Street.

OSTEOMYELITIS OF THE FRONTAL BONE

AS A COMPLICATION OF FRONTAL SINUSITIS

H. P. MOSHER, M.D.

BOSTON

Osteomyelitis of the frontal bone is one of the most dreaded of surgical diseases and one of the most fatal. In some parts of the country osteomyelitis of the frontal bone as a complication of infection of the frontal sinus is a rare disease. In my locality the fulminating type, and most of our cases fall into this class, is fairly common. Osteomyelitis of the long bones of the leg occurs over wider areas. When a disease is deadly, when patients suffering from it may come first to the general practitioner, the surgeon or the specialist and when recent work has been done on the disease the results of which are not yet in the textbooks, I feel that it becomes a subject of general interest. At least this is my hope. Also this is my alibi for presenting the subject today.

During the past seven years I have begun to approach these cases with more confidence. This is due to what I have learned by the systematic microscopic examination of specimens of osteomyelitic bone removed at operation during this period and by routine interval roentgenograms before and after operation. This continued study has made the source of the infection, its manner of spread and the speed of the spread clearer. This knowledge has led to the adoption by us in the fulminating type of a radical early operation which meets the disease head on instead of by the customary prolonged and generally unsuccessful pursuit from the rear. The infection in these cases does not wait while the surgeon watches and waits. It must be dealt with by an early "blitzkrieg."

So much by way of introduction. In former papers I have dealt with the subject of osteomyelitis of the frontal bone somewhat exhaustively. The space allotted for this paper permits only a condensed review.

THE ORGANISM

The organism in osteomyelitis of the frontal bone generally is *Staphylococcus albus* or *aureus*, and occasionally the streptococcus.

THE TYPES OF OSTEOMYELITIS

The disease occurs as two types—the fulminating, rapidly spreading form of which swimming is a frequent cause, and the less virulent localizing form which tends to burn itself out and form sequestrums. If the patient is septic, with pitting edema of the skin of the forehead half way to the hair line or at the hair line as often happens, I consider this as the fulminating type. Not having second sight, I cannot pick the case in which it is safe to operate conservatively and do what might be called a minor operation and hope for sequestration. I am not slipping into the grand manner when I say that on the time and the type of operation which the surgeon elects hangs the life of the patient.

THE DIPLOETIC VEINS

The diploetic veins of the skull are numerous and connect superficially with the veins of the scalp and have deep connections with all the blood sinuses of

the skull. The diploetic veins of the frontal bone are a continuation of the veins of the mucous membrane of the frontal sinus. Relatively they are very large and are absent from the frontal bone in only 3 per cent of the cases. The infection in the frontal sinus produces thrombophlebitis of the veins of the mucous membrane and of the diploetic veins of the frontal bone. The infection spreads to the bone marrow in which the veins are located. The branches of the diploetic veins run outward to the periosteum of the frontal bone and inward to the dura. The dura seems to attract the infection more strongly than the periosteum.

As everything in osteomyelitis of the frontal bone complicating frontal sinusitis harks back to infection of the mucous membrane of the frontal sinus and its walls, I shall have to bore the reader with the changes which infection causes in these structures. In no other part of the body do the pathologic changes caused by infection determine so definitely the course of the infection, its manner of spread and, most important of all, the type of surgery to be employed if it is to be successful and the time when this surgery is indicated.

THE BONE MARROW

There are two kinds of bone marrow—the yellow or fat marrow and the red or blood forming marrow.

Yellow marrow looks like a collection of fat cells. Between the fat cells there are narrow stellate spaces which are potential blood lakes. The cells lining the stellate spaces are capable of great activity in the production of fibrous tissue.

The red bone marrow, instead of having the empty look of the fat marrow, is crowded with every type of blood cell and every ancestor, immediate and remote, of the various types of blood cells. It is a bewildering maze not as yet fully deciphered. It still offers a fertile field for dispute among the experts. The diploetic veins run in both fat and red marrow.

THE CHANGES PRODUCED IN BONE MARROW BY INFECTION

The changes which infection produces in bone marrow occur in a definite order. The veins in the fat marrow enlarge greatly and often break, causing hemorrhage in the marrow space. Very early, so early that it almost seems to occur at the same time, the veins enlarge and a protective fibrosis begins in both the yellow and the red marrow. If the infection wins out over the protective fibrosis, patches of bone die and form sequestrums. In the neighborhood of a sequestrum the osteoblasts work hard to form new bone. As an added means of protection in nature's fight to conquer the infection, a layer of new bone made up of very fine trabeculae is often laid down over the dura. This, however, is so often found to be infected that it seems to be more of a carrier of infection than a barrier to its spread.

The only thing in this picture that is not familiar is the early protective fibrosis which forms in the marrow cells. On seeing it, one feels that nature is doing its best for the patient from the very beginning.

SIGNS AND SYMPTOMS

As osteomyelitis of the frontal bone is in most cases a complication of acute infection of the frontal sinus, there are classic signs and symptoms which go with this condition. Pitting edema of the skin of the forehead (Pott's puffy tumor) is the first sign of involvement of the frontal bone. Microscopic examinations of bone

specimens have shown that the limit of the edema is a practical guide, and the only guide in fact, to the limit of infection in the bone marrow. In fulminating cases the edema quickly extends to the hair line. The patient's temperature rises according to the amount of toxins absorbed from the infected veins and marrow spaces. X-ray examination shows a cloudy frontal sinus and gives the number and position of the diploetic veins. As it takes from seven to ten days for bone necrosis to occur, the x-ray film is not positive for osteomyelitis until this time has elapsed.

When the edema is localized and does not extend, as happens in the rare case in which trauma is the cause of the osteomyelitis, the infection of the bone marrow may also be localized.

The microscopic examination of osteomyelitic bone specimens has given another practical point, namely around an area of necrosis the infection extends radially for from $1\frac{1}{2}$ to 2 inches. The applied value of this finding is evident.

COMPLICATIONS

Few surgical infections have more possible and immediate complications. Unlike osteomyelitis of the long bones, which is often tempestuous enough, osteomyelitis of the frontal bone has the dura and the brain as neighbors. This means that extradural and subdural abscess, meningitis and brain abscess are common complications and are always in the offing. In osteomyelitis of the tibia the infection runs along under the periosteum as it does in infection of the frontal bone and the marrow also is infected, but the tibia has not the bad acting neighbors which the frontal bone has. The old saying about a lighted match near a powder keg aptly applies to osteomyelitis of the frontal bone, only there are two powder kegs to blow up instead of one.

SURGICAL TREATMENT

When edema of the skin of the forehead extends to the hair line, as it quickly does in fulminating cases, I believe that the surgical treatment of choice is the removal of practically the whole of the frontal bone. I should do this even if the edema extended only half way to the hair line. Laterally removal of the bone should extend to the external angular process of the frontal bone on both sides. It is neater craftsmanship to remove the bone in one piece.

THE CUTANEOUS INCISION

The median T incision gives the best exposure and the best drainage. The stem of the T should begin at the hair line.

The arms of the T should be made at the upper limits of the eyebrows, not through them. A split eyebrow comes together poorly when the operation for the correction of the operative deformity is done. The area of bone to be removed is marked out with the electric burr and the burr holes are connected by means of the Gigli saw or rongeur. Usually the bone dissects easily from the superior longitudinal sinus. The greater part of both the front and the posterior wall of both frontal sinuses is removed in order to let the sinus obliterate. This I believe is the surest way to obliterate the frontal sinus, even in nonosteomyelitic cases.

The triangular skin flaps are sutured to the scalp and the wound is left wide open. The dura is protected with paraffin gauze. For most operators fancy and fashion have determined the solutions used on the dressings if anything other than salt solution is employed.

One by one bactericidal vaccines have appeared and have been used with much trumpeting, only to disappear from the literature in a short time.

I hold that it should be routine practice to open both frontal sinuses and remove the anterior and posterior walls of each. Both sinuses are usually infected or well on their way to infection. In order for one to be sure of what is going on both sinuses have to be opened. The x-ray film is an unreliable guide on this point.

When the bone to be removed has been marked out with the burr, it is not uncommon for the patient's condition to become poor. The operation is thereupon stopped and the patient given a transfusion on the table, to be repeated if necessary when he reaches his bed. This means that donors should have been selected to be available at once.

THE TIME OF CLOSURE OF THE OPERATIVE WOUND

From my experience I feel that three months is as early as closure should be attempted. Secondary operations in a number of cases have been necessary when a shorter period was tried. During the waiting period for the performance of the plastic repair the edges of the bone defect are watched by x-ray examination for recurrence of the osteomyelitis. This waiting period is hard for the patient because the preliminary deformity is often marked.

In one of the early cases in which closure was done at six weeks the patient had jacksonian convulsions at irregular intervals for a few months. I am wondering whether, had closure been delayed, the fibrous tissue which replaces granulation as the end result of the healing process would not have been more evenly distributed and not given the localized pressure which caused the convulsions.

THE REPAIR OF THE OPERATIVE DEFORMITY

The operation for osteomyelitis of the frontal bone is easy. The hard thing about it is to make up one's mind when to operate and what type of operation to use. The plastic repair, on the contrary, is the hardest of the surgical procedures called for in dealing with this condition. The repair of the deformity is not a job for the beginner in plastic surgery. Fortunately my associates and I have Dr. Kazanjian, who is anything but a beginner. The first step in the repair is to free the cutaneous flaps and the periosteum and bring the edges of the periosteum together as close as possible and then approximate the cutaneous edges neatly. After a wait of from twelve to eighteen months for bone regeneration in the operative defect, the deformity is corrected by the insertion of a bone implant or implants, as the case may require. At first these were taken from the crest of the tibia; now Dr. Kazanjian takes the implant from the crest of the ilium, because this has the right curve. A large piece is used to make the lower part of the reconstructed brow. Above this a smaller piece is placed. If this does not prove to give sufficient correction, at a later period cartilage or fat is used to supplement the bone. After this series of steps the deformity is corrected fully 90 per cent. The net result of all these operative measures in 80 per cent of the cases is a live patient and a moderate and bearable deformity.

At this point I wish to remind the ophthalmologists that osteomyelitis of the frontal bone has been known to follow orbital abscess. In a few cases the pus in the orbit is not really an orbital abscess but comes from the frontal sinus by means of a break in the floor of

this sinus. In most cases of true orbital abscess the infection originates in the ethmoidal labyrinth and should be dealt with by an external operation on the labyrinth. What might be called the Italian method of treatment, universally practiced up to a few years ago, consisted in repeated stabbing of the orbit above and below the globe of the eye, often boxing the compass a number of times. The usual result was that recovery took from six weeks to six months. At times, however, osteomyelitis of the frontal bone resulted. I know of a recent case of orbital abscess treated in this inadequate fashion which ended up with osteomyelitis of the frontal sinus, then of the frontal bone. This was followed by brain abscess and death. I am confident that the examination of the old hospital records of any eye clinic would uncover a number of such cases.

REPAIR OF THE BONE DEFECT

In our cases nature's repair of the operative defect has been good only in young patients; in adults it has been very slow. Dr. Kazanjian suspects that we have maltreated the periosteum in the first stage of the operation. We were then thinking more of circumventing the infection than of the operative deformity. Now that we are surer of what to expect from operation in these desperate cases, he feels that more care should be given to preserving the periosteum at the first operation and in freeing it and bringing it together in the plastic operation.

Sprinkling bone dust on the dura is an old procedure. It was used successfully during the World War. Skillern uses it in connection with primary closure of the operative wound.

COMMENT

There are several unsolved questions in the management of osteomyelitis of the frontal bone: Is there any place for the conservative operation in osteomyelitis of the frontal bone? Is primary closure ever permissible? Is there any way of telling at the outset of a case whether it is to be of the sequestering, mild, localizing type or whether it is of the fulminating, rapidly spreading type almost sure to be quickly complicated with extradural or subdural abscess, or brain abscess and, unless halted in its tracks, nearly always fatal? Am I advocating an unnecessary, radical operation in the fulminating type of case?

First under consideration is the question of overoperating in the fulminating case. I have never had any sureness of result in these cases until the radical procedure as here described was adopted. The microscopic appearances in bone specimens speak for this type of operation. I shall wait for operators to get as good results with a more conservative operation before I give it up. In the fulminating cases I do not think primary closure of the wound is good practice.

The virulence of osteomyelitis varies in different parts of the country. This sounds like an alibi. A recent English writer reported seven cases of chronic osteomyelitis and stated that he had never seen a fulminating case. Reports in the literature of localizing osteomyelitis cured by conservative operations appear from time to time. A number of years ago a certain pugnacious gentleman stated that there was sequestration in all his cases. He has recently made equally strong statements on another subject—this time in connection with an operation on the ear. His listeners then and now were not in full agreement with him.

I should be willing to vote an antemortem halo to the man who can pick out at the onset and be right 75 per cent of the time which case will localize and not present complications.

As far as I can go in picking a case which suggests a conservative operation, it would be a case having the following history and one which shows the following signs and symptoms: The patient, child or adult, gives a history of trauma to the forehead. There is a localized area of pitting edema of the forehead, perhaps the size of a quarter (24 mm.), and the edema does not involve the front wall of the frontal sinus. The patient is not acutely ill. X-ray examination shows no involvement of the frontal sinus and there are no diploetic veins running from the edematous area. If the disease is of a week's standing the x-rays will probably show some necrosis of the bone under the edematous area.

Such a case would indicate and justify a conservative operation. Before operation pus might be withdrawn from beneath the periosteum where the swelling occurs, the organism identified and its virulence tested on animals. If the surgeon is right in his guess that the infection is of low virulence, a wait of forty-four hours for the result of the inoculation test would do no harm.

In a case of acute infection of the frontal sinus in which there is edema of the skin over the front wall of the sinus and no edema of the skin of the forehead, there is osteomyelitis confined for the moment to the front and posterior walls of the sinus. Microscopic studies have made it certain that in such cases there is infection of the posterior wall of the sinus as well as of the anterior wall. This means to my mind that after a portion of the front wall has been removed a part of the posterior wall should be removed as a routine. The object of this is to learn the condition of the dura and to determine whether or not an extradural abscess is present. When there is a necrotic area on the posterior wall it has long been the custom of operators to remove it, and many an unsuspected extradural abscess has been found in time to prevent osteomyelitis of the frontal bone or a brain abscess. For the patient's safety it is our duty to find out what is going on behind the posterior wall when edema of the anterior wall shows osteomyelitis of this wall.

In a case of mastoid disease, if the operator does not find enough pathologic change in the mastoid process to satisfy him he uncovers the lateral sinus.

A part of the posterior wall of the mastoid process lies against the lateral sinus; the posterior wall of the frontal sinus lies against the dura. One can tell the condition of the lateral sinus only by uncovering it. The same applies to the dura as it lies behind the posterior wall of the frontal sinus.

There are not a few men handling surgical cases who are not temperamentally surgeons. They do not think surgically. They are among those who use a hammer occasionally but never can drive a nail straight.

These sentences are inspired by the entrance of chemotherapy into the picture of osteomyelitis. It may change the picture of the treatment of osteomyelitis markedly. It will require good judgment and full surgical judgment to assign it its final role in this disease.

I have given the picture of osteomyelitis as I see it to date. Tomorrow is in the hands of Fate.

SUMMARY

The veins of the mucous membrane of the frontal sinus are continuous with the diploetic veins of the frontal bone. Compared with the thickness of the frontal

bone, they are of enormous size. In diameter they often measure one third to one half its thickness. The infection originates in the frontal sinus and is carried to the frontal bone by the diploetic veins. The branches of these veins run to the periosteum and cause edema of the periosteum and the skin. They also carry the infection to the dura, and the dura seems to attract the infection even more strongly than the periosteum.

If the infection is halted by a thrombus sufficiently long at any given point, there is necrosis of the bone and the formation of a sequestrum. If the edema extends to the hair line, as it generally does in a fulminating case, the infection in the bone marrow has advanced to the same point. The x-ray examination is positive only after necrosis has begun, and it is not positive until from seven to ten days after the onset of the pitting edema. From the surgical standpoint these are the days of hopeful surgery. If an area of necrosis is shown by x-ray examination or is found at operation, the microscopic examination of numerous specimens of bone in such cases has shown that the bone is actively infected for from 1½ to 2 inches beyond the necrotic area. The progress of the infection along the vein which is chiefly infected can be watched by means of the x-rays.

CONCLUSIONS

The operator who is doing his first operation on osteomyelitis of the skull should expect extradural abscesses as a matter of course. In fact he should expect more than this; he should be on the lookout for a subdural abscess or a brain abscess. The brain abscess, if present, is usually found later, or it comes later as a complication, but it is always threatening and should be watched for even at the first operation.

The more I see of fulminating osteomyelitis of the frontal bone, the more I believe that the whole face of the frontal bone should be removed, from the hair line to the eyebrow, as a routine procedure. Preferably it should be removed in one piece and the operation should start in clean bone; that is, at the hair line. However, if the patient is in poor condition and there is an area of necrosis, it is justifiable to work from the necrotic area outward, the bone being removed from 1 to 1½ inches in all directions from the necrotic area. Further, both frontal sinuses should be opened and the anterior and posterior walls of each sinus removed. I am firmly of the opinion that the lateral limit of the bone flap on each side should be at least the outer angle of each frontal sinus or, better, the outer angular process of the frontal bone on each side. The objection to this extensive removal is the deformity. However, since it has been proved that fully 90 per cent of these deformities can be corrected by modern plastic surgery, the surgeon should not allow his work to be restricted by the question of deformity. If he does, he will lose many or most of his cases of fulminating osteomyelitis of the skull.

The mark of osteomyelitis is written on the patient's brow. Cain, you remember, also had a mark on his brow. In the treatment of his patient let the surgeon beware lest he unwittingly reenact the role of Cain and deserve the same telltale mark when he too, by delayed or inadequate operation, kills his brother. Instalment operating in cases of fulminating osteomyelitis of the frontal bone generally results in the patient being repossessed by his maker.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. MACMILLAN AND MOSHER

DR. ARTHUR C. JONES, Boise, Idaho: Dr. Mosher's comprehensive paper on osteomyelitis of the frontal bone following sinus infection covered all the histology and pathology that I have been unable to find in any of our modern textbooks. I heartily concur with Dr. Mosher when he says that we must meet the fulminating type of osteomyelitis head-on instead of through the unsuccessful rear approach. I recently reported thirteen cases in the majority of which there was a *Staphylococcus albus* or *aureus* infection. I have also encountered the *pneumococcus*. I have found it necessary to remove the entire frontal bone in all my cases. The diploic spaces are tortuous and the osteomyelitis tends to follow the diploic spaces. I remove the osteomyelitic bone as far as the infection extends and then remove normal bone for at least one-half inch. This less radical procedure makes for less disfigurement and takes much less time. Dr. Mosher speaks of the mark of Cain being written on the patient's brow unless the radical procedure is followed. The follow-up pictures of these cases in which the flaps had been pinned back for two or three months have a mark that will tell the whole world that the unfortunate victim has encountered either a buzz saw or a thoroughgoing surgeon. Unfortunately, few of us have a Kazanjian to mop up after us. I envy Dr. Mosher and his staff the privilege of calling in such an eminent radiologist as Dr. Macmillan. Dr. Macmillan has emphasized the necessity of taking at least four views in these cases. Osteomyelitis is about ten days in advance of the x-ray appearances. When the nasofrontal duct becomes completely or partially blocked, the membrane thickened and its secretion retained within the sinus, it is always surprising how little increase there is in the density over the normal. For the most part I use the coronal incision and have been able to uncover as large an area of bone as in the T type of incision. I have had one death in thirteen cases and can see no reason for the T shaped incision, which causes the marked deformity. Of course, the picture of the plastic repair shown by Dr. Macmillan is very complimentary to Dr. Kazanjian. I have seen other pictures with more disfigurement than the ones shown.

DR. JOSEPH E. J. KING, New York: I agree with Dr. Mosher and Dr. Macmillan. There may be a little difference of opinion regarding a few minor details in the operative procedure. I am glad to hear Dr. Macmillan call attention to making x-ray films at short intervals in cases in which one may suspect development of osteomyelitis following disease of the frontal sinus. I have seen cases in which x-ray examination has been delayed so long that it became necessary to remove an enormous portion of the skull. Dr. Fred Law and I have noticed in reviewing films in reverse that a light area representing the point at which osteomyelitis is developing can be seen on the x-ray films at least ten or twelve days before the typical moth-eaten appearance is observed on the films. It is necessary to make only one postero-anterior film every day or two in order to detect this area a number of days before the subcutaneous pus pocket ("Pott's puffy tumor") makes its appearance. This thinned out area is due to involvement of the bone and is observed usually about three-fourths or 1 inch above the supra-orbital ridge, usually on one side. The operation can then be done, as Dr. Jones says, at a much earlier date and can be carried out with removal of less bone. I do not think there should be any discussion of osteomyelitis of the skull without an expression of thanks to Dr. McKenzie of London and Dr. Furstenberg for their splendid achievements in cases of osteomyelitis of the frontal bone. I agree with both that the so-called radical operation is the one of choice and that there is no place for what is termed the "conservative" operation. With the latter there is grave danger of extension of infection, which may be complicated by formation of a brain abscess.

DR. SAMUEL R. SKILLERN JR., Philadelphia: I have never seen a self-limiting type of osteomyelitis of the calvarium. How can one rule out the presence of a subdural abscess in the so-called silent area of the brain, the frontal lobes, unless the dura over this area is exposed? The removal of the pos-

terior sinus plate usually will demonstrate a subdural abscess; if not, at least it will allow any deep collections of pus to work their way upward into the operative field. The timid operator who treats the infected calvarium certainly is running the chance of a rapidly spreading infection of the bone with the likelihood of intradural complications. When one thinks that all such risks are lowered at least 80 per cent by a wide bone resection and that a regeneration with almost a perfect contour of the calvarium can be obtained from transplants of the calvarial bone, it seems to me poor judgment to take such chances. I have modified the Mosher U incision by carrying it through the upper edge of the hair of the eyebrow, then upward into the temporal hair. This incision minimizes the scarring of the forehead. The contents of the temporal fossa are avoided by dissecting the skin forward to the superior temporal ridge before incising the deeper tissues. The vitality of this soft tissue flap is retained by encapsulating it in a hot saline towel. In several cases in which the infection had infiltrated the bone, with or without intracranial complications, any remaining postoperative infection was seemingly controlled in from ten to fifteen days by the use of a bacterial antigen. This antigen was made from *Staphylococcus aureus* and *albus*, with lysed *staphylococcus* and *streptococcus* proteins in solution. I think that Dr. Mosher is ultraconservative in his prolonged open drainage. An early closure of the wound prevents the foreshortening of the flaps, does away with the necessity of pressure bandages and allows the skull to assume its normal shape. Granting that after the closure of the wound a collection of pus occurs, a diagnosis readily can be made as it causes a localized puffy tumor of the soft tissues. I do not hesitate to reopen the entire wound by breaking the newly formed connective tissue. I have had two such cases in which healing promptly occurred without undue disfigurement after the evacuation of the pus, followed by several days of drainage through a stab wound in the replaced flap. It is such a simple surgical procedure to take thin bone chips from the calvarium and plant them in their own environment that it seems to me unnecessary to replace the lost tissues by any foreign material.

DR. CORNELIUS G. DYKE, New York: As a radiologist, I wish to emphasize the importance of obtaining roentgenograms of the frontal and maxillary sinuses in the upright position. The patient must be erect in some cases so that secretions in the frontal sinuses may be visualized, for if the film is made with the patient horizontal no fluid level is formed and no evidence of infection may be visible in the roentgenograms. The lateral view is of considerable importance, and in the relatively few cases of acute frontal osteomyelitis following frontal sinusitis that have been seen at the Neurological Institute (about one year) the lateral view when slightly underexposed may show some localized edema of the scalp or slight decalcification of the bone in ensuing osteomyelitis. It should be emphasized that the complications of acute osteomyelitis of the frontal bone secondary to frontal sinusitis are uncommon, for, as Dr. Macmillan has stated, in twenty years he has encountered only eighty-six cases at the Massachusetts Eye and Ear Infirmary; in other words, about four cases a year in an institution that has an extremely active eye, ear, nose and throat service. However, only in this kind of hospital is it possible to collect a sufficient number of cases to determine which method of treatment is the best. In how many of the last sixteen cases, in which there was a mortality of 25 per cent, had sulfanilamide or one of the related compounds been administered?

DR. HARRIS P. MOSHER, Boston: I congratulate Dr. Jones on having microscopic sight in being able to tell normal from diseased bone. I have not acquired that facility yet. His cases, to my mind, are not of the fulminating type. I am ready to change my operation technic and change in any way that the adequate experience of others dictates. Dr. King supported me from the general surgical standpoint, and I have said a few things about the lack of the general surgical principles among some specialists. I was glad to hear Dr. King say that the patient can bleed to death if one is not careful to stop the bleeding as one is turning up the flap. I would agree with what he said about obliterating the frontal sinuses. If one does not obliterate it in these cases, one is

going to have trouble afterward, and the way to obliterate it is to take off both anterior and posterior walls. As Dr. Skillern says that I may be overconservative; if so, it is for him to prove it. He referred to chemotherapy. This is coming in. A note has been handed to me that sulfathiazole as a powder can be used in dressings. About Dr. Skillern's use of bone chips, this method was used in the World War and is worth trying again. Dr. Macmillan said that the x-rays were outmoded in osteomyelitis. I do not agree to that. Let me leave these thoughts with you: If you can find out which is a nonfulminating case, so much the better. Treat it accordingly. But watch the diploic veins. If one vein enlarges, showing that it is carrying infection, the bone carrying it should be removed. Especially watch the veins at the external angle of the frontal sinus. There have been some tragedies lately where these have not been watched.

DR. A. S. MACMILLAN, Boston: As Dr. Wilinsky in New York has said with regard to osteomyelitis being a limited disease, it is very often limited, but it is limited by the death of the patient. Within the last month, three cases of osteomyelitis have come in and have been treated by Dr. Champ Lyons at the Massachusetts General Hospital, in which he used heparin to prevent thrombophlebitis by increasing the clotting time, and sulfathiazole as a chemotherapeutic agent. His results in these cases, so far, have been startling, and we should watch for his paper on this subject.

DIABETES INSIPIDUS

TREATED BY THE SUBCUTANEOUS ADMINISTRATION
OF A SUSPENSION OF PITRESSIN TANNATE
IN OIL

JAMES A. GREENE, M.D.

AND

L. E. JANUARY, M.D.

IOWA CITY

It has been known for several years that solution of posterior pituitary controls the manifestations of diabetes insipidus. The pioneer work of Farini and Ceccaroni¹ and of von den Velden² demonstrated the efficacy of the hypodermic administration of solution of posterior pituitary, and Blumgart³ showed that spraying the solution into the nose was also effective. Furthermore, intranasal insufflation of the powdered whole gland controls the symptoms, as was shown by André and Lucie Choay.⁴ It was found by Kamm and his co-workers⁵ that pitressin contained the active antidiuretic substance.

The subcutaneous administration of solution of posterior pituitary or pitressin appears to be the most effective method of treatment. Warkany and Mitchell⁶ quoted Nobécourt and Ducas's statement that it is effective in 95 per cent of the cases. Certain very disagreeable side effects, however, such as pallor, diarrhea, palpitation, headache, nausea, intestinal cramps and increased blood pressure often occur. These side effects and the necessity of giving the injections very frequently make the prolonged use of such therapy impracticable.

Nasal insufflation of the powdered whole gland is often more convenient and less painful, but in the severe case it may be required from six to eight times a day and at least one time during the night.

Methods to produce slow absorption of hormones have been shown to be desirable in certain endocrine deficiencies. It seems to us that diabetes insipidus is such a disease. We have been able to find only two reports of efforts to prolong the effect of the antidiuretic principle of the posterior pituitary gland. Wankmüller⁷ administered hypodermically a posterior pituitary preparation dispersed in vegetable and animal oil to three patients with diabetes insipidus. A single injection controlled the symptoms for from three to five days. The injection twice a week of 1 cc. of a water-in-oil emulsion of concentrated liquid pituitary extract prepared by Court and Taylor⁸ controlled the symptoms in one case.

The present report is concerned with the effect of the subcutaneous administration of pitressin tannate suspended in oil,⁹ on three cats with experimentally produced diabetes insipidus,¹⁰ on two patients with the idiopathic form of diabetes insipidus and on one with diabetes insipidus which was thought to be a manifestation of lipoid granuloma. Pitressin tannate is a water-insoluble chemical combination of a pressor fraction of the posterior lobe of the pituitary gland with tannic acid. The pressor fraction is precipitated with tannic acid, and the precipitate is removed by filtration and washed and dried, all under aseptic conditions. Five pressor units of pitressin tannate are suspended in each cubic centimeter of peanut oil. The p_H of the solution is that of oil. The antidiuretic effect is one of the subjects of this report. In the cats, only the effect on

It is to be noted from table 1, which shows the effect of the subcutaneous administration of the material to cats, that an injection reduced the urinary output and increased the urinary specific gravity for from three to five days. Sufficient time was allowed between injections for the urinary output and specific gravity to

return to the control level. Actually the effect was even more prolonged, as demonstrated in table 2, which shows the daily urinary output and specific gravity in the case of cat 3 of table 1, following the administration of pitressin tannate in oil. The rise in specific gravity during the first day was greater than the decline in the urinary output, whereas, as the effect subsided, the specific gravity declined more rapidly than the urinary output increased. Some effect was demonstrable, therefore, in this animal for seven days, although the maximum effect occurred for only three days. The same was true for the other animals, although to a lesser degree.

Of the patients observed, the first was a boy 16 years of age whose symptoms had been controlled previously by hypodermic injections of solution of posterior pituitary and later by the intranasal insufflation of 25 mg. of the powdered whole gland four times daily. The daily urine volume during insufflation treatment varied from 2,000 to 3,000 cc., and the specific gravity from 1.010 to 1.015. It is to be noted from table 3, which compares the effect of intranasal insufflation of the powdered whole gland with subcutaneous administration of pitressin tannate in oil on this patient, that the manifestations were better controlled with the latter method of treatment. Not shown in the table is the duration of the effect of the administration of 1 cc. of this material. This varied from forty-eight to eighty-two hours and averaged fifty-seven hours. During the eight days of treatment covered by table 3, injections were repeated before the complete disappearance of the effect of the previous one. After the patient left the hospital the injections were repeated only as often as necessary to control his symptoms. He reports that

1 cc. is required every sixty to seventy-two hours. There were no side effects from the use of pitressin tannate in oil, although the manifestations of the syndrome were controlled more completely. The arterial pressure was not increased but there was an apparent increase of the urea clearance.

The second patient was a boy aged 17 years who was refractive to the intranasal insufflation of the powdered whole gland even when as much as 200 mg. was administered at one time. His symptoms were adequately controlled by an injection of 1 cc. of solution of posterior pituitary every twelve hours. The resulting headache, however, was so pronounced that after one year he discontinued the drug. The effect of administering solution of posterior pituitary hypodermically in 1 cc. doses two times a day, and of pitressin in 1 cc. doses two and three times a day, compared with the effect of administering pitressin tannate in oil in 1 and 1.5 cc. doses every other day, is shown in table 4. The effect of 1 cc. of pitressin tannate in oil lasted from thirty to fifty-three hours and averaged forty-four hours. The duration of the effect was not noticeably prolonged by increasing the dose to 1.5 cc. but the symptoms were better controlled. The symptoms were as well controlled when pitressin tannate in oil was administered every other day as when three injections of pitressin were given daily. There was no appreciable effect on the blood pressure or urea clearance, and headache did not occur. After the patient left the hospital the symptoms were controlled satisfactorily by an injection of 1 cc. every forty-eight to fifty-two hours.

The third patient was a woman aged 39 who was also refractive to the intranasal insufflation of the powdered whole gland, but her symptoms were well controlled by the injection of 1 cc. of solution of posterior pituitary every twelve hours. Pallor, nervousness and the passage of several watery stools frequently followed an injection. The results of the use of pitressin tannate in oil are shown in table 5. The duration of the effect of 1 cc. varied from thirty-two to forty-four hours and averaged thirty-seven hours, whereas 2 cc. prolonged the effect to from sixty-four to sixty-eight and one half hours. A very disagreeable sense of

hypodermic needle for the injections. There was no reaction at the site of the injections. Nevertheless it is advisable to vary the site of the injections. The patients were easily taught to administer the preparation themselves.

SUMMARY

Pitressin tannate in oil was administered to three patients with diabetes insipidus and to three cats with experimentally produced diabetes insipidus. The duration of the effect was ascertained, and the efficacy of this method of treatment was compared with that of other preparations of the posterior pituitary gland.

The duration of the effect in the cats varied from three to seven days, and in the patients from thirty to eighty-two hours. The effect on the manifestations of the disease in the patients was equal to that of other preparations of the posterior pituitary gland and there were no disagreeable side effects.

THE CHEMICAL AND MECHANICAL PREVENTION OF SYPHILIS AND GONORRHEA

PRELIMINARY STATEMENT BY THE SPECIAL JOINT
COMMITTEE APPOINTED BY THE AMERICAN
SOCIAL HYGIENE ASSOCIATION AND
THE UNITED STATES PUBLIC
HEALTH SERVICE

H. H. HAZEN, M.D., WASHINGTON, D. C., CHAIRMAN; IRA V. HISCOCK, C.P.H., Sc.D., NEW HAVEN, CONN.; P. S. PELOUZE, M.D., PHILADELPHIA; WILLIAM F. SNOW, M.D., NEW YORK; HANS ZINSSER, M.D., BOSTON; RAY H. EVERETT, L.L.B., WASHINGTON, D. C., SECRETARY.

The Committee was requested to review the history and present status of the prevention of syphilis and gonorrhea by chemical and mechanical means and to make such recommendations as seemed desirable at the present time. The Committee has had several meetings in New York and Washington, has reviewed the published material dealing with its field of study and has heard testimony from representative members of the Army Medical Corps, the Navy Medical Corps, the United States Public Health Service, state health officers, the medical profession, representatives of Negro medical and public health groups, medical schools, voluntary health organizations, religious organizations, educational organizations, social welfare agencies and civic organizations.

The Committee is cognizant of the fact that chemical and mechanical prophylaxis is only one phase of preventive medicine. The prevention of syphilis and gonorrhea by chemical or mechanical means is supplementary to and not a substitute for the prophylaxis of these diseases by educational measures which employ ethical and religious motives. Nor does chemical or mechanical prophylaxis justify any relaxation of efforts to reduce to a minimum exposure to infection by discouragement of prostitution and other forms of sexual promiscuity. In the case of syphilis and gonorrhea, as with other communicable diseases, the best and surest method of prevention of infection is the avoidance of exposure. Educational, religious, sociologic and legal activities which tend to prevent exposure to infection are of great importance. At the same time, however, the Committee is fully aware of the fact that sexual promiscuity is a very important factor in their

TABLE 5.—Effect of Pitressin Tannate in Oil on Patient 3

Experimental Period	No. Days	Average Intake, Cc.	Average Output, Cc.	Average Specific Gravity	Urea Clearance	Average Blood Pressure
No therapy.....	3	6,530	7,250	1.001	82%	130/80
Pitressin tannate in oil, 1 cc.....	9	2,060	1,130	1.022	97%	118/76
Pitressin tannate in oil, 2 cc.....	7	2,060	1,470	1.021	88%

"uneasiness" was experienced following the administration of 2 cc. Unfortunately, no measurements of the blood pressure were made during this period of study. No disagreeable side effects were noted after a dose of 1 cc. and there was no appreciable effect on the blood pressure or urea clearance.¹¹

The viscosity of the oil at room temperature requires that the ampule be immersed in warm water for several minutes and thoroughly shaken before the material is withdrawn into the syringe. It is preferable to use a 20 gage needle for filling the syringe and an ordinary

11. Since this paper was submitted for publication, two additional patients with idiopathic diabetes insipidus have been treated. The first was a 17 year old girl and the second a 24 year old man. In the first case the symptoms were controlled for from fifty-one to sixty-eight and one half hours (average, fifty-six hours) by 1 cc. of pitressin tannate in oil and, in the second, for from fifty to seventy hours (average, fifty-five hours).

spread. To decrease the number of carriers among this group of men and women, chemical and mechanical prophylaxis is necessary and hence is complementary to educational measures.

The place of chemical and mechanical preventive measures is at the point where educational, religious, social and legal efforts have failed to prevent exposure to infection. At that point preventive medicine offers reasonably efficient methods of prevention, which, if correctly applied, will in the majority of instances prevent the exposed person from becoming infected and from becoming a possible source of infection to those with whom he may later have contact. Thus not only one individual but that individual's family and community may be relieved of the burdens—medical, social and economic—of syphilis and gonorrhea. The employment of chemical and mechanical prophylaxis will preserve the efficiency of men required for defense or service of the nation in time of peace or of war. This being the case, it becomes the moral obligation of sanitarians to urge the wide dissemination of all available knowledge regarding such procedures.

After carefully reviewing the available scientific data as to the efficiency of various means of chemical and mechanical prophylaxis, the Committee makes the following specific recommendations:

THE CHEMICAL AND MECHANICAL PREVENTION OF SYPHILIS AND GONORRHEA¹

1. Safest method.
 - A. Use a condom of standard type.
 - B. Thoroughly wash the genitals and adjacent parts with soap and water as soon as possible (the sooner the better, but within one hour at most) after removal of the condom.
2. In the absence of a condom.
 - A. Thoroughly wash with soap and hot water as already described.
 - B. After urination, inject 6 cc. of 2 per cent strong protein silver solution, or other efficient, nonirritating germicidal solution into the urethra and hold for five minutes.
 - C. Rub 33 per cent ointment of mild mercurous chloride (calomel ointment) into the genitals and adjacent parts.

COMMENT²

The habit of cleanliness materially reduces the risk of infection. For the proper application of 2 B and C, skilled attention and use of a syringe are necessary. Prophylactic treatment of this type can be given by physicians, by some clinics, and in prophylactic stations where they exist.

The Committee emphasizes the fact that the foregoing suggested preventive measures are not 100 per cent successful. Their efficacy depends first on the reliability of the materials used. A defective condom does not give the same degree of protection as a sound article. The strong protein silver solution or the mild mercurous chloride may not be of the proper strength or may be inactive. Second, washing and application of chemicals may be delayed too long after exposure. Drunkenness may prevent correct application of any of these methods. It may be stated, however, that when these methods are followed correctly they will in the majority of instances prevent infection with syphilis or gonorrhea.

The medical profession and public health agencies, both official and voluntary, bear a heavy responsibility in the matter of the prevention of syphilis and gonorrhea by chemical and mechanical means.

Since these methods are efficacious they would, if widely understood and correctly utilized by those who expose themselves to the danger of infection, result in a great diminution of syphilis and gonorrhea and would thereby greatly reduce personal, family and community disasters and the economic losses that result from these infections.

It seems clear, therefore, that health education with regard to syphilis and gonorrhea should include simple, frank and explicit directions as to chemical and mechanical prophylaxis. This information should be included in its proper setting and in appropriate language.

It seems apparent also that, in addition to instructing the public regarding this preventive medical method, civilian, military and naval, medical and health authorities have the obligation to provide the facilities through which chemical and mechanical prophylaxis may be made available when and where needed. The authorities also have the responsibility for preventing the commission of fraud through the sale of worthless products to the public for the prevention of these diseases.

Finally the Committee is impressed with the fact that there are many unsolved and administrative problems within the scope of chemical and mechanical prophylaxis and the provision of adequate facilities for these procedures. It is considered that research in this field should be continued.

Clinical Notes, Suggestions and New Instruments

ASPIRATION OF SPUTUM FROM ADULTS

W. J. AUGER, M.D., TORONTO

During the past three years a new aspiration method of obtaining sputum at the Hospital for Sick Children has been in use. With one attempt it is usually possible to obtain sufficient sputum from the larynx or nasopharynx for direct examination and cultural purposes. The apparatus consists of a glass syringe, a catheter and a simple valve arrangement which permits powerful intermittent suction. By use of this method it has been learned that in children the nasopharynx is an ideal source for obtaining sputum for typing pneumococci in early cases of pneumococcal pneumonia, while sputum from the larynx is more suitable for examination in cases of tuberculosis, whooping cough or pneumonia due to a mixed infection.¹ The type of pneumococcus found in the nasopharynx has agreed in most cases with the type found in exudates, blood cultures and lung cultures at postmortem examination whenever these examinations have been possible. The only difficulty with this method is that in about 12 per cent of cases two types of pneumococci are to be encountered on direct examination, one type probably acting in the role of pathogen. Occasionally three types are to be found.

In view of these observations a study was made of expectoration of pneumonia patients among adults at the Toronto General Hospital through the courtesy of Dr. Duncan Graham. There were two objectives: The first was to learn whether sputum was obtainable from those patients who said that they could not cough or expectorate. This is frequently the case when the patient is too weak or irrational. Too often the

¹ The directions for the prevention of syphilis and gonorrhea apply to the prevention of all other venereal diseases as well.

² In this initial report the Committee has purposely avoided going into detail, believing that only general principles should be discussed. In the full report detailed methods will be given at length.

technician complains to the intern that the specimen received was not expectorated but was salivated. The latter problem is of interest in the study not only of pneumonia but also of tuberculosis. The second objective was to learn whether secretion from the nasopharynx would yield large numbers of pneumococci as in children and whether this method of obtaining sputum offered any short cut in the early diagnosis of pneumococcal pneumonia.

METHOD

Thirteen patients with pneumonia from the wards of the Toronto General Hospital were chosen over a period extending from April 1 to May 30, 1939. These were patients from whom the intern in charge was unable to obtain any sputum or, if he did, the sputum obtained was found in the laboratory to be unsuitable for direct examination. On notification of such cases, I attended the patient and obtained specimens of secretion from both the larynx and the nasopharynx by the aspiration method. The sputum was examined directly by smear and for the quelling phenomenon. It was then cultured on a blood agar plate, carbon dioxide being used.² (The mouse cultural method was not used.)

ASPIRATION METHOD

The construction and operation of an "aspirator" has already been described in a pediatric journal;¹ a short review will be presented here. The operation is essentially the same for adults except that more cooperation is expected, and the assistance of a nurse is not usually necessary. The apparatus consists of a 50 cc. syringe, a 2 inch piece of soft rubber tubing of three-sixteenths inch inside diameter with a small hole cut in one side (to act as a simple finger valve), a 2 inch piece of glass tubing of one-fourth inch outside diameter to act as an indicator for the sputum, and a catheter designed for either nasal or pharyngeal passage (see diagrams). All these materials can be obtained in any hospital supply room.

By the nasopharyngeal method the catheter (a number 9 or 10 French catheter) is inserted into the nasopharynx until it is judged to be in the "adenoid" area. Suction is commenced by having the operator hold the barrel of the syringe in the left hand and with the forefinger cover the window of the soft rubber tubing which connects the syringe with the glass tubing. The piston of the syringe is withdrawn with the right hand. At the end of the outstroke the finger is removed from the hole in the rubber tubing and the piston is shoved back into the syringe. In this manner the air is short circuited and the sputum is not returned into the nasopharynx. After repeated intermittent suction in this manner, the sputum will be seen to rise into the glass connection. Then the catheter is removed from the nose and placed in a sterile test tube. The sputum is forcibly ejected into the test tube by reversing the process, namely the forefinger covers the valve on the instroke of the piston and is removed on the outstroke. The thumb and forefinger of the right hand should grip some of the piston beyond the handle to prevent driving the piston through the end of the barrel during the process of ejection. The catheter is left in the test tube and is taken to the laboratory for further examination. The nasal method can be used to obtain sputum from the larynx, but the bore of the catheter is small and liable to be obstructed by thick sputum.

The laryngeal method employs a catheter of fairly stiff rubber tubing 4 by 5 inches long and of one-eighth inch inside diameter with a notched tip. This catheter allows for the collection of large amounts of sputum. The suction principle is essentially the same as in the nasopharyngeal method but is performed faster and more energetically. Some experience is required on the part of the operator to achieve best results. The patient is asked to open his mouth and cough. With the operator holding the syringe and valve in the left hand, the right hand at first directs the catheter to the base of the tongue while the patient is coughing. When the catheter is in position with its tip at the base of the tongue and above the opening of the larynx, the right hand changes position and pulls and pushes the piston as in the nasopharyngeal method. When the catheter is heard

to "catch" on the expectoration or when sputum is seen to rise into the glass connection, the catheter is removed and the sputum ejected into a sterile test tube. This procedure may have to be repeated before sufficient sputum can be obtained. This method is more irritating to the patient but at the same time one is sure that the sputum has come from the larynx or the trachea. In some cases the catheter does not catch any sputum but the patient is able to expectorate afterward, owing to the irritation of the cough reflex. This method should be done about two hours after meals. A cellophane mask covering the face should be worn by the operator.

A simpler method of aspirating sputum from the larynx is to use a sputum trap in conjunction with a machine suction apparatus. The sputum trap is constructed of an obstetric bulb with a 5 to 6 inch throat catheter attached to its lower end and the tube from a suction machine to the upper end. The catheter is directed to the back of the throat with the right hand, the left hand being left free to use a tongue depressor (the operator standing to the right of the patient). The sputum is aspirated in large quantities into the glass obstetric bulb and is removed from the bulb in the laboratory by attaching syringe and finger valve to the upper end and drawing and expelling saline solution in and out of the bulb. This method requires little experience, and its only disadvantage is in the requirement of a cumbersome machine suction apparatus. One

The assembled nasal and throat catheters and their uses.

distinct advantage of this technic, however, is that it leaves the left hand free to retract the tongue, so that the right hand can more accurately direct the tip of the catheter. This method has only recently been devised and used but has so far proved very satisfactory.

RESULTS

A comparison of the secretions from the nasopharynx with those from the larynx of thirteen adults with pneumonia was made. No conclusions were drawn as to the probable etiology of the respective pneumonias because of the small number in the series. The pathogenic bacteria recorded merely indicated their presence in nasal and laryngeal secretions.

In only two cases was the patient totally unable to expectorate voluntarily. In the other cases the sputum was insufficient because it consisted more of saliva than of purulent matter. In these cases the adult resembles the child and confuses expectoration with salivation. But, with the aspiration method, sputum with a minimum of saliva was always obtainable in all thirteen cases whether the nasal or the laryngeal route was used. The sputum was always sufficient for direct smear, Neufeld test and cultural methods.

The laryngeal method seems to be the easiest and most satisfactory for obtaining large amounts of sputum, particularly when the patient is weak or irrational. This is in contrast to children, in whom the nasopharynx is usually full of purulent secretion. It may be explained by the fact that the adult is uncomfortable whenever there is nasal obstruction and is continually blowing

2. Auger, W. J.: A New Method of Culturing Sputum on Solid Media Using Carbon Dioxide for the Isolation of Pneumococci, *Brit. J. Exper. Path.* 20: 439 (Dec.) 1939.

his nose or clearing his nasopharynx to rid himself of this feeling. Because large amounts of sputum relatively free from saliva were obtained from the larynx in patients when voluntary expectoration had failed, this method is recommended for getting suitable sputum from tuberculous patients. The laryngeal method has been particularly useful in infants and children in this respect.

In only one case were pneumococci more numerous in the nasopharyngeal secretions than in the laryngeal. There were eight cases of pneumonia with pneumococci in the sputum. In most cases the type of pneumococcus or other pathogenic bacteria found in the back of the nose agreed with that found in the larynx and also in about equal numbers. In children, on the other hand, in cases of early pneumococcal pneumonia, the nasopharyngeal secretions have been found to contain larger numbers of pneumococci than the laryngeal secretions.¹ This may be due in part to the relative absence of adenoid tissue in the adult. It is felt however that, if a stiff catheter with a curve to reach the roof of the nasopharynx could be constructed and inserted, perhaps foci of infection in the sinus recesses of the adult nose would yield interesting information. The secretions from the nose were usually freer of mouth organisms than laryngeal secretions. This is due to the throat aspirator unavoidably picking up mucus from the back of the throat. However, this can be partially remedied by careful washing of the sputum. In one case no likely etiologic organisms were isolated. The patient had received sulfapyridine for thirty-six hours before the sputum was aspirated. This illustrates the value of obtaining sputum before chemotherapy is started.

COMMENT

This study is admittedly based on a small number of cases and no conclusions should be made without further trial; nevertheless the ease with which large amounts of sputum could be aspirated from the larynx of patients who found it difficult to expectorate voluntarily seemed to justify the publication of this method. Since considerable bacteriologic experience is necessary for the examination of the sputum and some practical experience is required to operate the laryngeal aspirator, it is recommended that one person should both obtain and examine the sputum. This is to insure that suitable sputum reaches the laboratory.

With the advent of chemotherapy in the treatment of pneumonia there is a tendency to ignore sputum examination. While sulfapyridine may be administered without regard to the type of pneumococcus, for prognostic evaluation the type of pneumococcus may be of significance. In cases of streptococcal pneumonia sulfanilamide may be the drug of choice. In cases of pneumonia due to a staphylococcus or to *Bacillus influenzae*, the treatment and outlook are uncertain. This would indicate that early sputum examination is essential for prognosis and research in the treatment of pneumonia. On the other hand, proper sputum is essential for laboratory examination. A direct smear from purulent matter can in most cases anticipate the results from the cultures. Much time and labor may be saved in the laboratory by care in obtaining sputum at the bedside.

SUMMARY

A brief study was carried out on thirteen adults with pneumonia who reputedly could not cough or bring up satisfactory sputum for examination.

In all thirteen cases sufficient sputum was obtainable from either the larynx or the nasopharynx by the use of the aspiration method.

No advantage was found in nasopharyngeal secretions as compared with secretions from the larynx in the typing of pneumococci in pneumonia among adults.

The laryngeal aspiration method of collecting sputum, whether obtained by syringe and finger valve or by a sputum trap and machine suction, has been suggested for adults when voluntary efforts at expectoration have failed. This method is also recommended for obtaining sputum from tuberculous patients.

It is suggested that the person who examines the sputum in the laboratory should obtain the sputum.

ACUTE INFECTIOUS POLYNEURONITIS FOLLOWING PNEUMONIA

ALEXANDER LEON LOURIA, M.D., AND HARRY MANDELBAUM, M.D.
BROOKLYN

A rapidly extending paralysis ultimately involving all four extremities in a flaccid paralysis developed suddenly on the fourth day following the crisis of an uneventful case of bronchopneumonia. This infrequent sequel, difficult of recognition at its inception, is hereby reported:

REPORT OF CASE

History.—S. B., a boy aged 16, who entered the Jewish Hospital of Brooklyn on Dec. 4, 1938, had always enjoyed good health except for an uncomplicated scarlet fever at the age of 10. Six days before entering the hospital he complained of headache, weakness and lassitude. The temperature rose to 104 F. and he began to cough without expectoration. There was no chill. The temperature ranged between 100 and 104 F. daily. The day before admission to the hospital, he complained of pain in the left side of the chest on deep breathing and on coughing.

Examination.—On admission the patient was well developed and did not appear very ill; there was no dyspnea, cyanosis or jaundice. The pharynx was deeply injected; the tongue was moist and slightly coated. Some impaired resonance to percussion was obtained below the angle of the left scapula, and moist rales were evident at the end of inspiration at this site. The heart appeared normal, the abdomen was soft and the viscera were not palpable. There was no nuchal rigidity, no alteration of the tendon or superficial reflexes, no sensory changes and no cranial nerve palsies.

Course.—The temperature ranged between 102 and 103 F. daily. There was not much cough and occasionally he would raise a thick grayish sputum. Repeated examinations of the sputum showed no pneumococci; no hemolytic streptococci were obtained on culture; nondescript, indifferent streptococci were found. On the second day following his admission, dulness, bronchial breathing and many crepitant rales were noted in the right axilla and right interscapular region. The left lung was clear. X-ray study at this time showed bronchopneumonic infiltration of the base of the right lobe. Epistaxis occurred on the second and third day of his hospital stay.

In the absence of any specific typing and because no disturbing symptoms had arisen, he was given no specific medication, nor had any medication been taken before admission. The elevation of temperature continued for four days; on the fifth day it precipitately dropped from 103.4 F. to normal, and it remained normal thereafter. Blood counts during this period showed a red blood cell count of 4,800,000 and a leukocyte count of 9,000; there were 60 per cent polymorphonuclear cells, 20 per cent band forms and 20 per cent lymphocytes. Urine examinations showed no pathologic features.

Four days after the temperature had dropped to normal (fifteen days after the onset of pneumonia) he suddenly found himself unable to raise his arms sufficiently to feed himself. Examination showed weakness of both arms, especially the proximal muscle groups. The grip of each hand was diminished; the left was involved to a greater extent than the right. The following day it was noted that the pupils were irregular; they reacted promptly to light and in accommodation. The eyegrounds showed slight haziness of the disks. Slight lateral nystagmus was present, but it was easily exhausted. There was definite weakness of all four extremities, more marked in the shoulder and pelvic girdles. All the deep reflexes were lost. The cremasteric and abdominal reflexes were lost. There were no alterations in sensation or muscle tenderness. The patient did not complain of pain.

A spinal tap was performed on December 15 (two days after the onset of the paralysis). The initial pressure was 110 mm. There was a sharp rise and fall of the initial pressure with successive straining, jugular pressure and abdominal pressure; 8 cc. of spinal fluid was removed. It appeared crystal clear. There were 8 lymphocytes; the Wassermann and colloidal gold tests were negative; the chemical analysis showed a total protein

From the medical service of Dr. Louria, the Jewish Hospital.

of 42 mg. and a sugar content of 63 mg. per hundred cubic centimeters. No organisms were grown on culture of the spinal fluid. The following day, December 16, he complained of pain in both shoulders and arms and numbness and tingling of both hands. But little voluntary action remained in the extremities. The palate was noted to deviate slightly to the left, but this cleared in two days. At this time some pharyngeal weakness was evident as well as some weakness of the right facial muscles. Tests for electrical reactions of degeneration (faradic current) were performed on all muscles and were found within normal limits.

During the following week he complained of considerable pain in both arms and shoulders; some atrophy was now apparent in most of the muscles but appeared to be most marked in the hands. No fibrillary twitchings were noted. The pharyngeal weakness and the slight facial palsy cleared by the end of the third week.

On January 7, twenty-five days after the onset of the paralysis, the pain in both shoulders and arms was less. He was mentally clear. There was no nuchal rigidity; the pupils were slightly irregular. The eye grounds were normal; there were no cranial nerve palsies. Some muscle tenderness was noted. There were no fibrillary twitchings; muscular atrophy was slightly more marked. The tendon reflexes of the upper extremities and the abdominal reflexes were gone, the cremasteric reflexes and tendon reflexes of the lower extremities had returned to normal. There were no sensory disturbances. At no time was there any loss of sphincteric control. An orthopedic examination at this time revealed the following details: In the right upper extremity there were some atrophy of the deltoid, marked weakness of the external rotators and moderate weakness of the internal rotators of the arm; the triceps and the biceps action were reduced 50 per cent; there was marked loss of dorsiflexion at the wrist; flexion at the wrist was good; there were complete loss of extension of the fingers and marked weakness of the flexors of the fingers. In the left upper extremity there were marked weakness and some atrophy of the shoulder and arm; the external rotators were almost completely paralyzed but the internal rotators functioned about 60 per cent normally; the biceps and the triceps functioned about 40 per cent of normal. There were complete loss of extension of the fingers and considerable loss of flexion of the fingers. The lower extremities showed a slight degree of atrophy; flexion of the thighs was weak, abduction and adduction were good; the function of both knees and ankles was good; bilateral pes cavus was evident; the toes were retracted.

Subsequent Course.—Improvement progressed slowly. After the sixth week he no longer complained of pain, although some muscle tenderness was still evident. During the seventh week he was able to sit in a chair; during the following week he could walk with assistance. He was discharged on Feb. 5, 1939, for convalescent care and rehabilitation. At the end of the third month he was again able to feed himself and walk without assistance.

Treatment.—Twenty-four hours after the onset of paralysis, thiaminehydrochloride therapy was begun; he received 6.6 mg. intramuscularly four times daily for the first ten days; for the next two months he received a similar dose by mouth four times a day. A trial course of triple typhoid vaccine was given without appreciable benefit. The orthopedic consultant fitted him with appliances to prevent deformities until recovery was complete.

Diagnosis.—Among the diagnoses considered, the most probable were acute anterior poliomyelitis and acute infectious polyneuritis. The sudden appearance of flaccid paralysis involving the extremities was suggestive of poliomyelitis. However, the absence of fever, leukocytosis and constitutional symptoms, the absence of pleocytosis in the spinal fluid, the symmetry of the paralysis in contrast to the patchy asymmetry of the poliomyelitis, and finally its duration beyond the period where poliomyelitis usually halts, served to rule out poliomyelitis.

COMMENT

Acute infectious polyneuritis, also called acute infectious polyneuritis, was originally described by Sir William Osler¹

in 1892. However, it was not accepted as an entity until the World War, when successive reports appeared in the literature (Patrick,² Kennedy,³ Bradford, Bashford and Wilson⁴).

While the etiology is not known, the theory of a virus as the responsible cause finds considerable favor—a virus with a predilection for the peripheral neuron. Wilson⁴ and his co-workers isolated a virus and transmitted the disease to monkeys. In a large number of cases there was a history of a preceding infection. In the thirty-five cases reported by Gilpin, Moersch and Kernohan,⁵ 50 per cent had a preceding infection of the upper respiratory tract or influenza.

The essential pathologic change is a patchy degeneration of the myelin sheath of the peripheral nerve, with fragmentation of the axis cylinder and with no evidence of inflammation. The dorsal root ganglions may show lymphocytic invasion.⁵ Pathologic changes on rare occasions occur in the anterior horn cells and in the brain⁶ but the cord changes never resemble the lesions of anterior poliomyelitis.⁷ Cobb and Coggeshall⁸ summarily state that the axon seems to be more severely involved than the nerve cell, which obviously does not die and permits subsequent regeneration to take place.

During the clinical course, following recovery from a transitory infection, usually involving the upper respiratory tract, there is a latent period ranging from a few days to several months during which there are no premonitory symptoms. Then suddenly weakness and paresthesias of the extremities appear, the lower more often than the upper limbs being the site of involvement. There are no constitutional symptoms and no fever. Characteristically there is a rapid widespread involvement of all the extremities causing a flaccid paralysis of varying degree of severity. The facial nerve not infrequently becomes involved, unilaterally or bilaterally.² The deep reflexes are diminished or lost. Sensory symptoms are not marked, objective sensory changes are usually lacking and sphincteric control is usually not disturbed. Involvement of the cranial nerves other than the seventh is rare. No fibrillary twitchings are noted in the involved muscles. Atrophy, when it occurs, is the result of disuse.

McIntyre⁹ separated the cases into four groups; group I A, with rapid onset and rapid recovery; in these cases there frequently was seventh nerve paralysis; group II A, which ran a steady down hill course with early death; group III, with a long drawn out course and ultimate incomplete recovery; and group IV, which slowly progressed to ultimate death from bulbar involvement. In most of the cases satisfactory recovery takes place within six months or a year. In the cases reported by Bradford, Bashford and Wilson⁴ the mortality rate was 26.6 per cent.

The laboratory is of assistance in establishing the diagnosis. The spinal fluid is clear, not under increased pressure, shows no pleocytosis and characteristically shows an increase in the total protein. Madigan and Marietta⁶ observed the changes of the protein content of the spinal fluid in a case; the initial spinal fluid showed a total protein of 18.4 mg. per hundred cubic centimeters; it increased gradually to 122 mg., then gradually declined to normal (from 15 to 45 mg.). In all the cases reported by Gilpin, Moersch and Kernohan⁵ the total protein was elevated (from 100 to 1,800 mg. per hundred cubic centimeters) and the cells varied from 1 to 80, all lymphocytes.

SUMMARY

On the fourth day following the crisis of an uneventful case of bronchopneumonia, there suddenly appeared paralysis of the upper extremities. This was quickly followed by involvement of the lower extremities, with flaccid paralysis of all four

THE RELATIONSHIP BETWEEN THE PATHOLOGIC
CHARACTER OF THE LESION AND THE
EFFECTIVENESS OF CHEMOTHERAPY

As experience with bacterial chemotherapy has accumulated during the past few years there has been a tendency on the part of most writers to think solely in terms of bacteriologic specificity in predicting or interpreting chemotherapeutic effects. Experimental results clearly show that different bacteria vary in their general susceptibility to the bacteriostatic effects of compounds of the sulfonamide group. However, in evaluating chemotherapeutic effects in animal infections and in man it is advisable to keep in mind that from a practical standpoint the pathologic characteristics of the lesion under treatment are also of great importance. Diffuse infections characterized by the rapid multiplication and dissemination of invasive bacteria in tissues of relatively normal architecture or in fluids closely resembling normal serum or lymph are likely to respond favorably to chemotherapy. This group includes, specifically, the early stages of cellulitis, lymphangitis, erysipelas and lobar pneumonia and probably also acute pyelonephritis and infections of the cerebrospinal fluid. Whether the causative organism is a hemolytic streptococcus, a staphylococcus or a pneumococcus makes some difference in the choice of a drug, perhaps, but these lesions are generally susceptible regardless of the bacterial species. Sulfapyridine, which is apparently a more polyvalent drug than sulfanilamide, will be effective in the great majority of infections of this pathologic type, and the bacteriologic aspects are of secondary importance.

Infections of serous and synovial membranes such as peritonitis, pleuritis and suppurative arthritis (at least in their early stages) constitute another broad group of lesions which are generally susceptible to sulfonamide therapy. Diffuse non-necrotizing peritonitis in animals and in man is likely to respond to treatment whether the organism is a hemolytic streptococcus,⁷ a pneumococcus,⁸ a colon bacillus² or even a Welch bacillus.⁹ Pleural effusions which commonly develop during lobar pneumonia rarely progress to the formation of empyema in patients who have been treated with chemotherapeutic substances. Flippin and our group at the University of Pennsylvania treated 160 patients with type I pneumonia during 1938 and 1939, and the incidence of empyema was only 1.9 per cent in contrast with the "prechemotherapeutic" incidence of 13 per cent reported by Reimann for this type.¹⁰ I have seen several cases in which clinical and laboratory evidence of acute suppurative arthritis developed during the course of a septic infection and in which the arthritis subsided under chemotherapy without the necessity for surgical drainage. Infections of serous and synovial cavities have certain definite pathologic features in common, the most important probably being the early mobilization of an abundant protective mononuclear cell reaction, which Gay¹¹ has shown is a highly effective mechanism in killing bacteria. This cellular response is given added time to become mobilized when a substance like sulfanil-

amide is present to hold down the multiplication and toxin production of the infecting organisms. Furthermore, the lining membrane has a good blood supply and is resistant to the necrotizing action of proteolytic enzymes liberated during inflammation by leukocytes and bacteria. It has been shown that one of the most important factors conditioning the magnitude of sulfanilamide action is the amount of products of tissue or bacterial proteolysis in the environment. The capacity of endothelial surfaces to resist proteolysis is therefore another probable reason for the effectiveness of sulfonamide therapy in these infections.

So far I have considered the pathologic types of infectious lesions which are generally susceptible to sulfonamide therapy. It will be noted that they are all early lesions in which treatment by surgical methods has been more often harmful than beneficial. There are, on the other hand, certain definite types of lesions which are quite resistant to chemical treatment. The most conspicuous in this group are the localized abscesses of soft tissue or bone. Bacteriologic specificity again has only a limited significance in the chemotherapy of localized necrotic lesions in soft tissue, bone, pleura or peritoneum. They all tend to be resistant, regardless of the type of organism present. Use of the appropriate drug may have some effect in preventing spread of the infection to adjacent tissues and may actually mask the clinical signs and symptoms of the abscess. Prolonged treatment for a month or two may sometimes allow sterilization of the abscess, but as a general rule such a course will be unpractical and inadvisable. Premature withdrawal of the drug is likely to be followed by reactivation of the infection.

Suppurative thrombophlebitis is another type of pathologic lesion which is comparatively resistant to chemotherapy. The causative organism may be *Streptococcus haemolyticus*, *Streptococcus viridans* or *Staphylococcus aureus*. Chemotherapy will cause blood cultures to become sterile in a case of septicemia or spinal fluid cultures to become sterile in a case of meningitis, but the existence or development of a suppurative thrombophlebitis will make reinfection probable and will in any event greatly prolong the period of recovery.⁶

The practical significance of the emphasis which has been placed here on the pathologic characteristics of surgical infections is that it indicates the place of surgery in the present day treatment of infections. At some time during the clinical course of almost any surgical infection there is likely to develop a pathologic lesion which will not be susceptible to chemotherapy. When this lesion is dealt with surgically, at the right time, the course of treatment can be shortened (which is highly advantageous in preventing toxic reactions) and the chances of final recovery may be considerably increased. The process requiring surgical attack may be an abscess at the primary site of infection or in a lymph node draining the area. It may be a focus in a long bone or in a mastoid. Furthermore, the surgeon who recognizes the limitations of chemotherapy will not be tempted to employ any drug as a substitute for surgery in a necrotizing process such as acute appendicitis. He will limit the application of chemotherapy in this condition to the postoperative treatment of peritoneal infection beyond the limits of the appendix.²

The limitations of sulfonamide therapy in terms of pathology are well illustrated in the staphylococcal infections. One may as readily account for the relative resistance of staphylococcal infections on the basis of

their pathologic characteristics as on the basis of the comparative resistance to sulfonamide bacteriostasis which the staphylococcus possesses. The conspicuous features of staphylococcal infection are tissue necrosis, suppurative phlebitis and the early tendency to form suppurative metastatic lesions. As a general rule the recovery of patients with staphylococcal septicemia, even with treatment by a drug having a high experimental antistaphylococcal effect, will probably depend on whether the primary distributing focus can be detected and drained. It is doubtful whether the specificity of any new compound in the sulfonamide group will be sufficient to overcome the protective "antibacteriostatic" environment which the staphylococcus provides for itself in localized lesions.

Surgical treatment has not by any means been supplanted by sulfonamide therapy. On the surgeon still rests the responsibility for first detecting and then draining or removing the localized suppurative distributing foci which chemotherapy cannot successfully attack. The presence of one of the sulfonamide compounds in the tissue fluids of the potentially septic patient will help to protect him against the consequences of dissemination produced by whatever surgical procedure is necessary in eradicating the distributing focus. The masking of some of the diagnostic signs of infection by sulfonamide treatment appears to render the detection of obscure foci even more difficult than formerly, and new improvements in diagnostic technic may have to be developed. The sulfonamides are really effective principally against the invasive manifestations of infection which surgical treatment has in the past been more likely to aggravate than to cure.

In summary, it might be said that a lesion which is characterized by minimal loss of tissue architecture, and an exudate which is "serous," composed chiefly of lymph, bacteria and inflammatory cells, is likely to respond very rapidly to sulfonamide therapy. On the other hand, when the exudate is thick and purulent, having a high content of products of tissue proteolysis and many dead bacteria and phagocytes, the response to chemotherapy will be relatively slight except at the periphery, where bacteria are lodged in tissues which have not yet become broken down. Sulfanilamide will attack the invasive component of bacterial infections, but the localized abscess and the necrotic distributing focus are problems for surgical drainage or excision. In these areas the bacteria remain potentially invasive; if the inhibitory effect of the drug is removed and host resistance is still inadequate, reinvasion occurs.

GAS GANGRENE

Experimental results with sulfanilamide treatment of *Clostridium welchii* infections in small animals have not been encouraging. Long and Bliss⁹ and Stephenson¹² have shown that mice may be protected against lethal doses of the organisms administered intraperitoneally. However, the Welch bacillus produces its toxin in the presence of devitalized muscle tissue, and the invasive disease produced by intraperitoneal infection of mice is not at all comparable to the lesion of gas gangrene as it occurs clinically. When the bacteria are introduced intramuscularly, even after having been washed free from preformed toxin, the results have been uniformly negative. Erb¹³ in our laboratory could find no protection of pigeons with sulfanilamide given before and

after infection, in contrast to antitoxin, which was highly effective. Kendrick¹⁴ obtained similar results with guinea pigs, and Stephenson was unable to protect mice which had been infected intramuscularly. Bohlman's¹⁵ early report of recovery in three cases in which a clinical diagnosis of gas gangrene was made scarcely constitutes adequate proof of the specific value of the drug against *Clostridium*. For the present it would seem that our chief reliance should be on prevention of gas gangrene by débridement of susceptible wounds and administration of prophylactic antitoxin. It is possible that sulfanilamide treatment might have some value in limiting the activity of pyogenic cocci, which are known frequently to prepare the ground for gas gangrene. One would therefore be justified in using one of the sulfonamide preparations in conjunction with other measures, while recognizing the fact that the drug perhaps has little effect on *Clostridium* itself.

THE PROPHYLACTIC USE OF SULFANILAMIDE

If pathogenic bacteria are implanted in a fresh wound they will, after a few hours, start to multiply, utilizing the tissue fluids in the wound as a culture medium. If there are foreign bodies or devitalized tissues in the wound, the environment becomes rapidly favorable for bacterial growth and toxin production.

Prior to the introduction of the sulfonamides it was recognized that the most important consideration in preventing wound infections was to employ gentle handling of tissues in operative procedures and to carry out thorough débridement and cleansing of grossly contaminated accidental wounds before bacteria had had time to start to multiply actively. The prophylactic use of the sulfonamide compounds in prevention of wound infection is a supplementary means of holding down the multiplication of bacteria which gain access to an operative wound or cannot be removed by débridement from a traumatic wound. Sulfanilamide action is maximal when the number of bacteria is small, the amount of devitalized tissue slight and the concentration of the drug high. Under these conditions there may occur restriction of the outgrowth of types of bacteria which are usually quite resistant to the bacteriostatic effects of the drug. If an effective concentration of the drug can be added to the tissue fluids of the wound before multiplication has actually commenced, the normal tissue defenses will have an opportunity to become mobilized.

The principle of prophylactic treatment is now being applied by the British Royal Army Medical Corps in the management of war wounds.¹⁶ It was reported in an official study¹⁷ that 70 per cent of fatal infections during the last war were due to hemolytic streptococci. It may be that in the current war the incidence of such infections can be greatly reduced. At the Hospital of the University of Pennsylvania we have for three years been using sulfanilamide by mouth in the prophylactic treatment of severe compound fractures. Infection has probably been prevented in some of these cases. Prophylactic sulfanilamide is now being used also in industrial practice in an effort to reduce the amount and duration of disability from infection following injuries

in shops and factories.¹⁸ While the theoretical value of such treatment cannot be contested, there are some real dangers to be considered from its indiscriminate application in all types of trivial injuries. Apart from the fact that toxic effects appear to occur more frequently and with greater severity in ambulatory individuals, there is the added danger that the drug will produce motor incoordination and other effects in the central nervous system. No person should be allowed to operate a machine of any sort while taking sulfanilamide. Therefore it would seem advisable to restrict the prophylactic use of sulfanilamide to patients whose injuries are sufficiently disabling to demand their complete inactivity.

Jensen, Johnsrud and Nelson¹⁹ have carried out a clinical and experimental study of the effect of implanting crystalline sulfanilamide into freshly debrided compound fracture wounds. When from 5 to 10 Gm. of crystals is placed in the wound before closure the drug concentration in the wound remains above 200 mg. per hundred cubic centimeters for more than thirty hours. Such a concentration would be highly effective in inhibiting the growth of even resistant organisms such as *Staphylococcus aureus* or *Clostridium* during a critical stage of wound repair. There was no evidence that the drug interfered in any way with wound healing. In their series, thirty-nine drug treated compound fractures healed without infection, while infection occurred in 27 per cent of ninety-four fractures treated by similar methods but without sulfanilamide. A distinct hazard in this application of sulfanilamide, particularly if amounts as high as from 15 to 20 Gm. are used, is the possibility of severe toxic reactions in hypersensitive persons. While it is unlikely that this danger would be sufficiently great to contraindicate the method if it were the only possible means of controlling infections in compound fractures, it will be important to find out whether local implantation gives better results in practice than oral dosage. Clinical studies now in progress may justify the use of crystalline drug implanted locally in the prevention of infection in other types of surgical wounds, including large hernias, lobectomies and pneumonectomies, and contaminated intestinal resections. But for the present it seems to me that local implantation of the drug should be used only to supplement oral administration and not in place of it.

THE PRACTICAL APPLICATION OF SULFONAMIDE THERAPY IN SURGICAL INFECTIONS

This section is an attempt to set down, within the limits of a brief review, some notes on chemotherapy as applied to types of infections commonly encountered in general surgical practice. The suggestions put forward are altogether tentative and subject to modification with new developments in this rapidly changing field.

General Considerations. — 1. Choice of Drugs: Sulfanilamide appears still to be the drug of choice in hemolytic streptococcus infections and in nonspecific prophylaxis because:

(a) The incidence of serious toxic complications is relatively low and patients are not usually nauseated by it.

(b) By altering dose schedules it can be employed to provide high blood concentrations for a short period or low blood concentrations for a long period.

(c) It can be administered subcutaneously in 0.8 per cent solution in physiologic solution of sodium chloride when oral administration is inadvisable and can be implanted locally without irritation.

In pneumococcal infections sulfapyridine and sulfathiazole are more effective than sulfanilamide. Of these two the latter is perhaps preferable because it is less likely to produce nausea and vomiting.

In staphylococcal infections the value of sulfanilamide is quite limited, partly because of the pathologic characteristics of infections due to this organism. While sulfathiazole and sulfamethylthiazole appear to be more highly bacteriostatic for staphylococci than sulfanilamide, the relative clinical value of these drugs has not yet been determined.

2. Dosage and Methods of Administration: The daily dose is divided into six fractions when given by mouth and four fractions when given parenterally. The amount administered varies with the severity and relative susceptibility of the lesion under treatment. It is usually from 6 to 10 Gm. the first day, from 5 to 7 Gm. the second day and from 4 to 6 Gm. the succeeding three days. If a clinical response is obtained within forty-eight hours and the lesion is one in which relapse appears to be unlikely, the treatment is stopped on the fifth day. If the response to treatment is slow, but nevertheless apparent within two days, the treatment may be continued for from six to ten days. If the lesion is a chronic one and prolonged treatment of more than two weeks appears desirable, the daily dose is usually from 2 to 4 Gm. For treatment of this type it might be desirable to use a compound such as azosulfamide or benzylsulfanilamide,²⁰ which liberates free sulfanilamide more slowly.

On rare occasions one is confronted with a patient displaying some of the signs of invasive infection but in whom a definite diagnosis cannot be made. In such cases a "therapeutic test" with one of the sulfonamides may appear to be indicated. If no evidence of a therapeutic response is obtained within forty-eight hours it is probable that further continuation of the drug will be futile and perhaps undesirable. The same rule probably should be applied in the treatment of invasive infections due to bacteria whose susceptibility to chemotherapy has not yet been determined.

Sulfanilamide is usually given by mouth. Solutions for parenteral use are prepared by adding 8 Gm. of crystalline sulfanilamide to a liter of hot physiologic solution of sodium chloride, which is then allowed to cool.

NOTES ON CHEMOTHERAPY IN THE PREVENTION AND TREATMENT OF SPECIFIC LESIONS ENCOUNTERED IN GENERAL SURGICAL PRACTICE

Diffuse Cellulitis and Lymphangitis.—Prophylaxis: Administration of sulfanilamide by mouth for five days is probably of value in severely traumatized, contaminated wounds and compound fractures, but only in conjunction with, and not as a substitute for, thorough débridement and cleansing of the wound. Local implantation of sulfanilamide crystals in compound fracture wounds has been reported to be very effective.¹⁹

Treatment: Sulfanilamide in full doses should be used for the first forty-eight hours, followed by gradually diminishing doses until the seventh day. The management thereafter will depend on whether or not

18. Brylski, F. J.: *Prontylin and Neoprontosil: Their Use in Industry*, Indust. Med. 8: 469 (Nov.) 1939.

localized abscess formation has occurred. Immobilization, elevation and heat should be used in conjunction with chemotherapy.

Acute Lymphadenitis.—Prophylaxis: Prophylactic treatment consists of the early treatment of cellulitis and lymphangitis.

Treatment: When suppuration is doubtful, sulfanilamide is given until fever and local signs of acute inflammation subside, usually for from seven to ten days. Complete resolution will not occur if pus is present. When suppuration is definite, sulfanilamide may be given for one or two days, after which the abscess should be incised and drained. Chemotherapy may then be continued for a few days, depending on whether there is any residual peripheral cellulitis.

Soft Tissue Abscess.—Prophylaxis: Early treatment of cellulitis may prevent abscess formation.

Treatment: Surgical drainage is indicated. Chemotherapy should be used only if cellulitis also is present.

Nonsuppurative Phlebitis.—Chemotherapy is of little value. Good results are being obtained from bandaging the affected extremity and from paravertebral sympathetic block.²¹

Suppurative Thrombophlebitis. — Prophylaxis: The avoidance of continuous venoclysis in septic patients is probably desirable.

Treatment: Chemotherapy is of limited value in attacking the local lesion but should be used in full doses in order to limit dissemination. Heparin may be of value in limiting propagation of the thrombus. Ligation of the vein proximal to the area of infection may be helpful in special cases.

Septicemia. — Prophylaxis: Chemotherapy and immobilization should be applied to early lesions likely to lead to septicemia. Surgical procedures should be avoided in diffuse cellulitis, but if unavoidable (as in acute tenosynovitis) the use of sulfanilamide before and after operation may help to minimize dissemination.

Treatment: Chemotherapy is indicated in full doses. If the drug is effective, marked clinical improvement is usually evident within forty-eight hours. The prognosis is much better if foci of distribution or localization can be drained. Frequent small (250 cc.) transfusions of fresh whole blood are probably helpful. Intravenous "double potency" bacteriophage²² is promising in staphylococcic septicemia, particularly in conjunction with chemotherapy.

Osteomyelitis.—Sulfonamide therapy may be directed against the dissemination of the infection but is probably of only limited value in the treatment of established bone foci. It should be used during and for a few days after surgical procedures likely to cause dissemination.

Pulmonary Abscess.—Chemotherapy is apparently of little or no value because the organisms are drug resistant and the lesions are characterized by extensive necrosis.

Infections of Serous or Synovial Cavities.—Chemotherapy is particularly successful in the prevention and treatment of infections of serous and synovial cavities. This is probably because of the highly developed local cellular defense, the resistance to necrosis of the lining membrane and the readiness with which adequate concentrations of the drug occur in the fluids.

Pleuritis and Empyema.—Prophylaxis: Chemotherapy might be of value if used before and after pneumonectomy or lobectomy. Chemotherapy of pneumonia tends to prevent empyema.

Treatment: Chemotherapy and drainage by aspiration may be used if the exudate is serous. Resolution without the necessity for open drainage is likely under these conditions. Rib resection and drainage will be required as soon as the exudate is frankly purulent. Sulfonamide therapy in small doses after operation may shorten the period of drainage.

Primary Peritonitis. — Chemotherapy should be started in full dosage after the diagnosis has been established by paracentesis or by exploratory laparotomy through an incision of minimal size.²³ Appendectomy should be avoided in these cases. The choice of drug will depend on the organism found. Other treatment directed against dehydration, distention, hypoproteinemia and electrolyte imbalance is of great importance.

*Peritonitis Secondary to Inflammation or Perforation of the Bowel.*²⁴—Prophylaxis: Sulfanilamide therapy has been recommended for one day before and for four days after intestinal resections.²⁴

Treatment: Sulfanilamide treatment appears to be of value in all cases of acute appendicitis which, at operation, show evidence of infection beyond the limits of the appendix itself. Appendectomy is essential. Chemotherapy may be instituted also in cases of peritonitis secondary to soiling of the peritoneum from other causes but only to supplement surgical and other therapeutic procedures of established value. In cases of peritonitis the drug is given parenterally until oral feedings are permissible.

Acute Suppurative Arthritis.—Chemotherapy should be started as soon as the diagnosis has been made, either on clinical grounds or by aspiration and study of the exudate. If drug therapy is started early in the disease the results are very good and surgical open drainage will probably not be necessary. (The treatment of rheumatic fever or rheumatoid arthritis with sulfonamide is contraindicated.²⁵ Treatment should be continued for about a week after all clinical signs of inflammation have subsided.

Meningitis. — Prophylaxis: Prophylactic treatment consists of sulfonamide treatment of otitis media, mastoiditis and invasive sinusitis, in combination with appropriate surgical measures. Chemotherapy alone will not insure against a late spread of infection to the meninges from a suppurative focus in bone or blood vessels but will sometimes mask the existence of such a focus.

Treatment: Chemotherapy should be instituted in full doses by mouth or parenterally. Some authorities recommend administration of the drug intrathecally as well.²⁶ The use of a drug having specific bacteriostatic effect on the causative organism may bring about marked clinical improvement and clearing of the spinal fluid, but relapse is very likely to occur unless the focus that feeds the spinal fluid can be drained or removed. Treatment should be continued in gradually diminishing doses for at least two weeks after apparent clinical

recovery. Most of the cures in meningitis due to hemolytic streptococci, pneumococci and staphylococci are a result of skilful and timely surgery in conjunction with chemotherapy and are not by any means due to the drug alone.

CONCLUSIONS

1. The pathologic character of the infectious lesion is an important factor in determining the effectiveness of sulfonamide therapy.

2. Surgical treatment is required in eradicating localized suppurative foci which are resistant to chemotherapy.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS. HOWARD A. CARTER, Secretary.

CONTINENTAL SHORT WAVE UNIT MODEL SW-200 ACCEPTABLE

Distributor: Bedford Surgical Company, Inc., 1326 Fulton Street, Brooklyn.

The Continental Short Wave Unit, Model SW-200, is used for medical and surgical diathermy. Pads, cuffs, inductance coil, surgical accessories and metal electrodes are supplied as standard equipment. The shipping weight of the unit is 175 pounds.

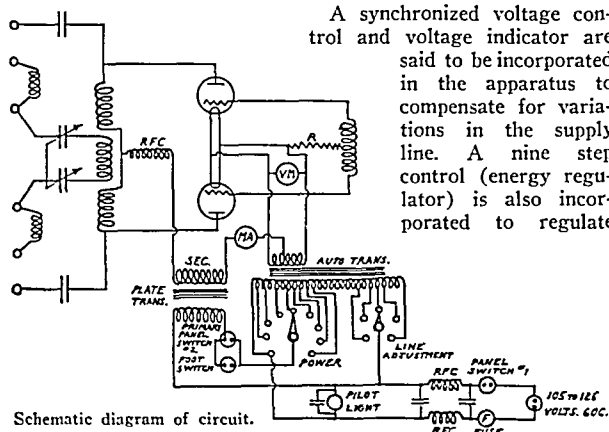

Continental Short Wave Unit, Model SW-200.

The firm states that the unit operates on approximately 12 meters and utilizes two tubes in a self-rectifying, push-pull tuned plate, tuned grid oscillating circuit. The tubes consist of two HF-120 oscillator tubes. The patient's circuit is inductively and capacitatively coupled to the oscillating circuit and is controlled by two variable condensers in series connected to both sides of the patient's outlets, coupled to a single control. In tests performed by the Council the power input was found to be 800 watts and the output 300 watts;

transformer temperature was 78.2 C. after the unit had been operated at full load for two hours. This temperature comes within the limits of safety prescribed by the Council.

A synchronized voltage control and voltage indicator are said to be incorporated in the apparatus to compensate for variations in the supply line. A nine step control (energy regulator) is also incorporated to regulate

energy to the patient's circuit. Three radio frequency chokes in the circuit are said to reduce radio interference.

Data concerning deep muscle temperature measurements was submitted by the firm and confirmed by the Council. The data are as follows:

DEEP MUSCLE TEMPERATURE MEASUREMENTS DOUBLE CUFFS

Technic: Double cuffs were placed 7 inches center to center, each equidistant from the thigh cannula. The cuffs were $2\frac{1}{4}$ by

19 inches, and three-fourths inch of felt was used for spacing. The current on the ammeter was 200 milliamperes plate circuit.

Average temperature of six tests: Deep muscle, initial 97.4, final 106.7. Oral, initial 98.4, final 98.6.

CABLE

Technic: Four turns of cable were placed 8 inches center to center equidistant from the thigh cannula with three-fourths inch felt and towel spacing. The plate reading was 200 milliamperes.

The average temperatures of six tests were: Deep muscle, initial 97.8 F., final 106.8 F. Oral, initial 98.3 F., final 98.6 F.

The Council report indicated that the Continental Short Wave Unit, Model SW-200, had been used almost daily on about fifteen different patients. It was found that the heat is just as effective as that of other short wave apparatus.

Clinical investigation of the unit by the Council revealed that spacers might well be used with the coil because of its marked flexibility and small diameter. The apparatus is easily adjusted and applied.

The Council voted to accept the Continental Short Wave Unit, Model SW-200 for inclusion on the Council's list of accepted devices.

B-L-B INHALATION APPARATUS ACCEPTABLE

Manufacturer: The Ohio Chemical & Manufacturing Company, 1177-1199 Marquette Street N.E., Cleveland.

The B-L-B Inhalation Apparatus with Helium-Oxygen Equipment is named for its designers, Boothby, Lovelace and Bulbulian. According to the firm, the advantages of the apparatus are a low purchase and maintenance cost, the efficient use of therapeutic gases, the ability to give therapeutically the desired concentration of oxygen between that in air and pure oxygen, the ability to administer efficiently helium-oxygen mixtures, the mechanical simplicity and ease of operation, and the portability of the apparatus.

The equipment supplied by the firm consists mainly of three parts, the B-L-B Inhalation Apparatus, a reducing regulator and flowmeter for pure oxygen, and a reducing regulator and flowmeter for helium-oxygen mixtures.

The inhalation apparatus is composed of the mask proper and a metal connecting and regulating device which joins the mask to a rubber reservoir rebreathing bag. Two types of interchangeable masks are available. The nasal type leaves the mouth free for talking, eating or drinking, which is an advantage in prolonged use. The oro-nasal type covers the nose and mouth and is for use by persons who have nasal obstructions or who are mouth breathers. In both types provision is made so that a suction tube can be passed through when it is desired to administer 100 per cent oxygen in combination with the use of the Wangenstein or Miller-Abbott suction method of intestinal decompression. The masks are available in two sizes.

B-L-B Inhalation Apparatus.

By the adjustment of three small portholes in the connecting and regulating device, it is possible to regulate the proportion of atmospheric air admitted to the apparatus which, in conjunction with the appropriate flow of oxygen or helium-oxygen mixtures, gives the desired mixture of the inspired gases.

In use, the compressed oxygen or helium-oxygen mixtures first pass through a reducing valve and flowmeter; next they enter the inlet tube of the B-L-B apparatus and are delivered through a tube to the lower end of the reservoir rebreathing bag. Then they pass into the nose chamber, through the connecting and regulating device, and are inhaled by the wearer. The exhaled gases pass down through the tubes and the connecting and regulating device, where a part of the gases pass out through

any holes that may be open in the rotary sleeve. The remaining portion passes downward into the bag, where it is mixed with the incoming gases.

When the bag becomes distended with the mixture of expired air and incoming gas, the slight pressure then produced permits the excess to escape through the expiratory valve. The expired air thus escaping will be from the latter part of the expiration and will contain the most carbon dioxide and least oxygen. That part of the expired air which passes into the bag first and contains the least carbon dioxide and the most oxygen is available for rebreathing. On the next inhalation the mixed oxygen and expired gases, further admixed with atmospheric air entering through the portholes, are again drawn in.

The Council investigated and used the apparatus clinically and found no objectionable features referable to its construction or to the claims made. Actual gas analyses bore out the stated claims as to efficiency. In patients for whom its use was undesirable, the fault was with the apparatus rather than with the method.

The Council on Physical Therapy voted to accept the B-L-B Inhalation Apparatus with Helium-Oxygen Equipment for inclusion on its list of accepted devices.

Council on Pharmacy and Chemistry

PRELIMINARY REPORT OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING PRELIMINARY REPORT, CONSIDERATION OF COBRA VENOM BEING POSTPONED BY THE COUNCIL TO AWAIT FURTHER EVIDENCE CONCERNING ITS USEFULNESS AND HARMLESSNESS. THE COUNCIL HAS LIKEWISE POSTPONED CONSIDERATION OF THE BRAND SUBMITTED BY THE FIRM OF HYNSON, WESTCOTT & DUNNING UNDER THE NAME COBRA VENOM SOLUTION (SECRETION OF NAJA) AND DESIRES TO EXPRESS ITS APPRECIATION OF THE COOPERATIVE SPIRIT WITH WHICH THE FIRM AIDED THE COUNCIL'S CONSIDERATION. PAUL NICHOLAS LEECH, Secretary.

COBRA VENOM SOLUTION (SECRETION OF NAJA) (HYNSON, WESTCOTT & DUNNING)

Hynson, Westcott and Dunning, Inc., presented for the Council's consideration Cobra Venom Solution (Secretion of Naja). The preparation is proposed for intramuscular injection as a slowly but persistently acting analgesic which lacks the chief disadvantages of morphine. When this report was prepared it was marketed in ampules of 1 cc., each of which represents 5 mouse units. A mouse unit is that amount of cobra venom solution which causes the death of a mouse of average weight of 24 Gm. in twenty-four hours.

The use of venoms or extracts of venomous reptiles as analgesics began about ten years ago when Monaelesser of New York learned that a Cuban leper who had been bitten by a tarantula experienced amelioration of painful and nervous symptoms. In Paris he gave cobra venom to 112 cancer patients in a dilution of 1:80,000 and noticed lessening of pain after four or five doses. Slower development, and even regression, of the tumors was reported at the same time. Since then the use of cobra venom for the relief of pain has been the subject of many investigations.

Nearly all the venoms derived from serpents for therapeutic use contain hemolysin, hemorrhagin, proteolysin and neurotoxin in widely different concentrations and ratios in different species and even in specimens from the same serpent under varying conditions. Cobra venom contains far greater amounts of neurotoxin than that of either the rattlesnake or the moccasin and on this basis rests its use as an analgesic. Chemically it contains the elements carbon, hydrogen, sulfur, oxygen, nitrogen and phosphorus. The dried venom yields 87.56 per cent of protein with the following fractions: globulin 20.31 per cent, albumin 39.69 per cent, primary proteose 11.31 per cent and secondary proteose 16.81 per cent. Lecithin (partly free) and cholesterol may also be found. The toxicity of the venom is attributed to the secondary proteose. Three enzymes have been demonstrated, a proteolytic one which is capable of digesting gelatin, casein, fibrin and crystallized egg albumin; a rennetic

enzyme, and one which may split lecithin. The hemolytic power of cobra venom is associated with a fraction composed of globulin and primary proteose.

The effect of cobra venom in the mammalian vascular systems varies with the species. Intravenous injection of the venom into cats anesthetized with dial causes a steep fall in blood pressure, the action being said to be due to obstruction in the pulmonary circulation without contributory heart failure. Injection into the femoral artery causes vasoconstriction of the limb. With survival there is recovery of the blood pressure followed by a slow secondary fall due to loss of circulating fluid, with hemorrhagic edema of the lungs and, in some cases, from heart failure. The effects in cats are different from those in dogs, the fall in blood pressure in the latter being due to vasodilatation rather than pulmonary obstruction, and permeability of the capillaries with loss of fluid causes an increase in the concentration of the hemoglobin. The fall in blood pressure in the dog induced by the intravenous injection of cobra venom is due to a peripheral action similar to that of peptone. Respiration is accelerated slightly by small doses but is decreased with large doses by paralysis of the phrenic nerve. Injection into the veins or lymphatics induces an action similar to that of curare. It has been reported that cobra venom causes the blood sugar to be increased in guinea pigs but has little effect in this respect in the rabbit.

Tissue activity has also been shown to be influenced by cobra venom. Low concentrations of the venom stimulate tissue growth in vitro, whereas high concentrations exert an inhibitive action. These effects are attributed to different types of enzyme action on fibrin. Changes in surface tension opposite in direction to those in viscosity are induced by injection of the venom, probably because of increase in the protein concentration in the plasma. In monkeys it has been shown that the alterations in the reaction of the plasma and the buffering are parallel, the result of carbon dioxide tension caused by the action of the venom on the respiratory center. Venoms and the avensoms of the cobra and vipers retard or cause to regress the growth of the Rous sarcoma in fowls, but the action is not specific. A certain inhibitory action is seen in mammals but large doses of the venom have no effect much beyond the point of injection on rapidly growing carcinomas in rats.

Macht and his co-workers have shown that cobra venom (a) inhibits the growth of the roots of lupin seedlings, indicating them to be protoplasm poisons, (b) suffers a rapid loss in potency when exposed to ultraviolet radiation, (c) stimulates and later depresses the ability of a rat to find its way to food in a maze, (d) facilitates mathematical calculations in man, (e) increases acuity of vision and widens the field for certain colors without affecting the size of the pupil, (f) slightly increases acuity of hearing, (g) stimulates the respiration and circulation in the cat but fatal doses cause death by paralysis of respiration, (h) exerts its analgesic action in the higher centers of the brain or on some lower synapses but not on the periphery, (i) is fatal to the cat if 1.35 mg. per kilogram of body weight is given intravenously, and to the frog if 0.01 mg. per 20-22 Gm. of body weight is given intraperitoneally, (j) antagonizes the convulsant action of picrotoxin and certain other convulsants that act on the medulla, (k) improves neuromuscular coordination and work, (l) usually increases the experimental contraction of the index finger, and in long continued large doses does not appear to impair the functions of the liver or of the kidney of the rabbit.

Varying degrees of success have been reported in the use of cobra venom for the relief of pain in cancer. Many agree that relief of the pain is usually obtained, and in some cases apparent regression of the tumors have been observed. However, the latter effect is doubtful. The types of cancer cases experimented with included cancer of the prostate, bronchus, stomach, lungs, colon and breast. Other diseases causing pain which were reported to be successfully relieved by venom therapy include trigeminal neuralgia, leprosy of the nerve type, rheumatoid arthritis and other forms of arthritis. However, cobra venom seems to be of little value where pressure on a nerve exists. Improvement of appetite, whether a direct effect or due to decreased use of the morphine which had been necessary in so many cases, has been noted. The use of cobra venom in parkinsonian syndrome has been more recently reported.

No serious complications have been reported following therapeutic injection, although local reactions are not unknown. A few investigators have seen headache, nausea, diarrhea, fever and a pain at the site of injection following the use of Cobra venom. No observable changes have been found in the red blood corpuscles, blood pressure, temperature, pulse rate or blood picture, nor has there been found any pathologic condition such as hemorrhage or infiltration, or effects on respiration or the gastrointestinal tract. Pigmentation, however, has occasionally been noticed, lasting for some weeks.

Apparently there are no true contraindications to the use of cobra venom for the relief of pain, but especial care is necessary with patients who have psychic disturbances or severe diseases of the liver or kidneys. No exacerbation of symptoms in cardiac, hypertensive or diabetic patients has occurred, nor has there been found any abnormality in urinalysis.

The technic of dosage is not simple and the optimum dose must be determined separately for every patient. It does not act uniformly as to degree and time in cases presenting approximately similar involvement. The dose is independent of age, well-being and other factors.

The manufacturer of Cobra venom solution, Hynson, Westcott and Dunning, Inc., submitted several clinical papers with the presentation of its preparation, but the Council does not believe that they afford sufficient evidence of a satisfactory nature on which to base an opinion concerning the therapeutic value of the venom. The directions in the specimen package circulars state that the first dose, 0.5 cc., should be injected intramuscularly, and 1 cc. on each of several successive days until definite relief of pain is noted. It is clear, however, that no fixed dosage after the first is available. The greater number of European observers have been influenced by the procedure of Monaesler and Taguet, who began with doses of about 2½ mouse units and gradually increased this at intervals of two or three days between injections. Some have attained doses of 20 mouse units or more, others have not exceeded 10 mouse units. The frequency of repetition employed is extremely variable. One must determine the single dose, as well as the frequency of repetition, for each patient so far as possible. Without careful supervision it would seem that the venom may do far more harm than good in many cases.

Ten ampules of the Cobra venom solution in a small box were submitted. These have been kept in the box; hence the conditions have been uniform for these ampules, but they show wide differences in color, and on standing different amounts of precipitate are seen. The firm's attention was called to this lack of uniformity, and the Council was informed that the differences are due to the preservative used. While it may be the cause of the precipitate, it does not explain the variability in amount. The firm wrote that the process of preparation has now been improved, but new specimens have not yet been seen. The firm submitted a list of 155 references, but with the exception of those of Macht and his associates there are only three clinical studies made by Americans and published in the United States of which the Council knows and which are suitable for analysis.

Cobra venom is certainly capable of relieving pain under varying conditions and appears to be of distinct value in giving relief from pain in cancer. It often fails completely, and it seldom, if ever, replaces morphine completely for any considerable time. It often causes pain of widely different degrees, probably owing to differences in composition, but this does not necessarily apply to the venom of Hynson, Westcott and Dunning, Inc. Among the disadvantages of Cobra venom which have been observed by European clinicians and others are pain of injection (intense at times), nausea, vomiting and diarrhea. However, Taguet and others have reported the absence of shock or other general or allergic reactions, though the records of patients treated number hundreds.

In summary, the Council considers purified Cobra venom to be of some value for the relief of pain, especially that of inoperable cancer (its use in the early stages would tend to delay curative measures); it does not displace morphine completely in more than relatively few cases but it is of value in these few; it appears to be of limited value in the treatment of tic douloureux and the various conditions commonly grouped loosely under the names of "rheumatism" and "arthritis"; its therapeutic effects are variable and uncertain in all painful conditions;

the disagreeable side actions, including nausea, vomiting, diarrhea and pain of injection—even intense pain at times, mentioned in medical journals—must be brought to the attention of those who use Cobra venom; it must not be recommended for those who are severely ill except those suffering from inoperable malignant tumors or from incurable disease; the optimum dosage (after the first single dose) remains to be determined; the effects are not immediate but may take hours to appear.

In view of the lack of sufficient evidence to warrant inclusion in N. N. R. at this time, the Council postponed consideration of Cobra venom and of the submitted brand and authorized publication of the foregoing preliminary report.

In accordance with the Council's custom, the adopted report was sent to the firm before publication. As a result of some correspondence certain editorial changes were made. The firm also informed the Council of its intention to double the strength of the marketed product from 5 mouse units to 10 mouse units per cubic centimeter without change in price.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

SOLUTION OF POSTERIOR PITUITARY (See New and Nonofficial Remedies, 1940, p. 386).

PITUITARY SOLUTION-U. S. P. (U. S. S. P. Co.).—A brand of solution of posterior pituitary-U. S. P.

Manufactured by U. S. Standard Products Co., Woodworth, Wis.

Ampul Pituitary Solution-U. S. P., 1 cc. (U. S. S. P. Co.).

Ampul Pituitary Solution-U. S. P., ½ cc. (U. S. S. P. Co.).

Vials Pituitary Solution-U. S. P., 10 cc. (U. S. S. P. Co.).

Vials Pituitary Solution-U. S. P., 30 cc. (U. S. S. P. Co.).

SULFANILAMIDE (See New and Nonofficial Remedies, 1940, p. 489).

The following dosage forms have been accepted:

Tablets Sulfanilamide, 5 grains-Wyeth.

Prepared by John Wyeth & Brother, Inc., Philadelphia. No U. S. patent or trademark.

Tablets Sulfanilamide, 7½ grains-Wyeth.

Prepared by John Wyeth & Brother, Inc., Philadelphia. No U. S. patent or trademark.

Tablets Sulfanilamide, 10 grains-Wyeth.

Prepared by John Wyeth & Brother, Inc., Philadelphia. No U. S. patent or trademark.

BISMO-CYMOL (See New and Nonofficial Remedies, 1940, p. 147).

The following dosage forms have been accepted:

Bismo-Cymol, 60 cc. Bottle: Each cubic centimeter contains bismo-cymol equivalent to 50 mg. of metallic bismuth, dissolved in olive oil.

Bismo-Cymol, 500 cc. Bottle: Each cubic centimeter contains bismo-cymol equivalent to 50 mg. of metallic bismuth, dissolved in olive oil.

PHENOBARBITAL (See New and Nonofficial Remedies, 1940, p. 134).

The following dosage form has been accepted:

Phenobarbital Tablets, 0.1 Gm. (1½ grains).

Prepared by The Smith-Dorsey Company, Lincoln, Neb.

SULFAPYRIDINE (See New and Nonofficial Remedies, 1940, p. 494).

The following dosage form has been accepted:

Capsules Sulfapyridine, 0.25 Gm. (3¾ grains).

Prepared by Parke, Davis & Company, Detroit. No U. S. patent or trademark.

SOLUTION LIVER EXTRACT CONCENTRATED-LILLY.—Now Solution Liver Extract-Lilly, 2 U. S. P. Units Per CC. (See New and Nonofficial Remedies, 1940, p. 329).

Ampoules Solution Liver Extract-Lilly, 2 U. S. P. Units Per CC., 3.5 CC.: Marketed in packages of four 3.5 cc. rubber stoppered ampoules.

SOLUTION LIVER EXTRACT PURIFIED-LILLY.—Now Solution Liver Extract-Lilly, 15 U. S. P. Units Per CC. (See New and Nonofficial Remedies, 1940, p. 330).

Ampoules Solution Liver Extract-Lilly, 15 U. S. P. Units Per CC., 10 CC.: Marketed in 10 cc. rubber stoppered ampoules.

PHYSICIANS NEEDED FOR INDUCTION BOARDS

After registrants are accepted by local draft boards they will be sent for physical examination to medical induction boards. About one hundred such boards will be set up throughout the country, about half of them near army posts and stations. Each board will consist of three internists, one general surgeon, one orthopedic surgeon, two ophthalmologists, one otorhinolaryngologist, one neuropsychiatrist, one clinical pathologist and one dentist.

As explained by Colonel Love (pages 1201-1202 of this issue), the specialists to be assigned to such service will probably include civilian specialists as well as reserve officers, who will be on temporary duty. Civilian physicians will be on a per diem basis and will be used as long as their services are required. It has been proposed that they be paid at the base pay of major with allowances for travel and subsistence while on duty. Physicians preferred for this service are those who, on account either of age or of physical infirmities or because of reasons affecting their civil life, cannot go into military camp. It has been tentatively estimated that the time required for this service might approximate twenty to thirty days in the period between October 16 and February 1.

In order to aid the Army Medical Department in securing physicians for this service, the Committee on Medical Preparedness requests physicians who wish to volunteer to write at once to the Committee on Medical Preparedness, 535 North Dearborn Street, Chicago, marking the envelop "Induction Boards."

VITAMINS FOR WAR

England, locked in the struggle of total war and conscious of the importance of maintaining at high levels the strength and courage of its people, has fortified margarine with vitamin A and restored calcium and thiamin hydrochloride (vitamin B₁) to flour.¹ This action was taken on advice from the Medical Research Council and with the recommendation of leaders in nutritional research. Sir John Orr² and Dr. J. C. Drummond³ were largely responsible. In consequence, ill effects from deficiency of calcium com-

pounds and vitamin B₁ will be minimized in England notwithstanding lower rations. Vitamin A will accompany whatever edible fats remain available, and calcium and vitamin B₁ will be supplied as long as any cereal food is left.

The slim margin that exists between man's physiologic requirements for vitamin B₁ and his intake of this vitamin has long been known; also the fact that storage of this vitamin is minimal and that debility quickly follows when men are deprived of it. The diets of half the population of England were found⁴ to provide a level of intake of vitamin B₁ less than that which the League of Nations Technical Commission regarded as necessary for adult men in peace time. That level was 300 international units a day. For soldiers, however, for men in factories and on the farms, in war time, for long work and short sleep, a level of 300 international units is certainly not optimal.

The Stiebling report from the United States Department of Agriculture⁴ revealed a large proportion of "poor" diets in peaceful America with its bursting granaries and troublesome problems of overproduction. The diets were poor in vitamins A, D and B₁ and in calcium. To some extent they were poor for lack of purchasing power, but to a large extent they were poor because of lack of skill in getting good food values for food expenditures. When white flour and sugar provide 50 per cent of the calories, as is the case in England and America, selection of a diet that can be called good, in the sense that it satisfies more than minimal requirements for vitamin B₁ and calcium, is almost impossible except for an expert.

Recent reports on induced vitamin B₁ deficiency⁵ bear directly on the importance of a liberal allowance of vitamin B₁ for a people engaged in war. Restriction of the intake of this vitamin in a group of healthy subjects, otherwise adequately fed, provoked, among other signs and symptoms, moodiness, sluggishness, indifference, fear, and mental and physical fatigue. The states of mind and body observed in these subjects were such as would be least desirable in a population facing invasion, when maintenance of stamina, determination and hope may mean defeat or successful resistance.

Other subjects in the experiment mentioned received thiamin hydrochloride in such an amount that their intake of thiamin would be almost, if not quite, up to the standard set for this vitamin by the League of Nations Technical Commission. These subjects remained in apparent good health for weeks, but when, at the end, more of this vitamin was administered—enough to raise the intake to 600 international units a day—alertness increased and measured capacity for physical work was almost doubled.

M., and Smith, B. F.: Observations on Induced Thiamine (Vitamin B₁) Deficiency in Man, Arch. Int. Med., to be published.

This suggests that efficiency for prosecution of a war can be increased by the simple expedient of providing a very little more of vitamin B₁ than the public is receiving. This subject is also receiving consideration by those responsible for our national defense.

USE AND ABUSE OF ADVERTISING BROCHURES

One of our colleagues who apparently has plenty of space at home decided about a year ago to save every piece of advertising literature in the field of therapy that came to him during 1939. A large closet was set aside for the purpose; the latest report indicates that material thus collected weighed over three hundred pounds. Even at the current price paid for waste paper, the collection will not pay for the cost of storage. The fact gives opportunity, however, for some philosophic considerations on the use and abuse of brochures circulated by manufacturers of proprietary products as their contribution to the education of the physician.

As examples of the printing art, many advertising brochures are good. As sources of scientific information in certain fields, some may be valuable. Some of the lithographs and four-color reproductions which illustrate anatomic appearances, physiologic functions and therapeutic technics are superior to anything that can be found in the available textbooks. Yet by no stretch of the imagination can any of these brochures be considered wholly scientific, since their purpose is obviously to sell specific products. Manufacturers are naturally averse to discussing in their brochures competitive products of the same type or alternative technics. They tell a story but seldom or never the whole story.

The manufacturer who reaches the general practitioner first and who accustoms him to the use of certain materials endeavors to retain his patronage for a considerable time. Hence the introduction of such substances as insulin and liver extract, which demand technical knowledge for determination of dosage and method of administration, is associated with the wide distribution by the manufacturers of extensive brochures discussing these matters. The introduction of new serums for use in pneumonia, and of sulfapyridine, has elicited a series of brochures dealing with these products. The newer anesthetics gave rise to theses dealing with the nature and composition of the products, as well as heavily illustrated brochures dealing with the technic of use.

As part of its function, the Council on Pharmacy and Chemistry of the American Medical Association has been accustomed to examine such brochures to make certain that the claims made are in accord with the acceptance of the product by the Council; thus the Council actually gives added prestige to brochures on products which are accepted. The difficulties involved in the examination of such a vast amount of material should be obvious. Indeed, some members of the

Council look askance on brochures that seem overelaborate as to production and illustration. It requires great time and effort to evaluate such monographs and to check and verify alleged scientific statements which seem to be more interested in selling than in science.

The whole field of medical publication is undergoing an obvious transformation. The speed of the times would seem to demand more in the nature of monographic publications dealing with a single subject and less of extensive textbooks which tend to become obsolete, at least in portions of their text, in a short time. Development of this trend for the monograph in the field of unbiased scientific literary production would be useful to the medical profession; it might lead to less abuse in the publication and distribution of brochures by commercial interests.

ACETYSALICYLIC ACID DEATHS

The only country in the world that permitted a patent for acetylsalicylic acid (aspirin) was the United States. The "Bayer" patent expired in 1917; since then the supply of acetylsalicylic acid or aspirin on the American market has been essentially of the same quality, irrespective of the manufacturer. Even after the expiration of the patent in 1917 it has paid the Bayer Company to continue the proprietary advantages gained thereby, and the concern has extolled, through advertisements and the radio, the virtues of acetylsalicylic acid for the self treatment of many disorders. Other firms have done the same. Probably no other drug, as widely used, has had fewer deaths reported following its use. Fortunately, most persons who take acetylsalicylic acid, in common with other salicyl compounds, experience a warning sign (tinnitus) if overdosage is imminent, so that the drug may be discontinued before these persons become seriously poisoned. In spite of the tremendous amount of self medication with aspirin in this country, comparatively little poisoning has been reported. No doubt, much harm indirectly has probably followed its indiscriminate use, in that conditions for which it was used were not remedied.

Since introduction of aspirin forty-one years ago by Dreser, many reports have appeared on the adverse effects which may follow its unwise use. These have included depression of the heart, habit formation, miscarriage in pregnancy, and idiosyncrasy causing such alarming symptoms as urticaria, pruritus, erythema and generalized angioneurotic edema. Cutaneous eruptions of various forms are not unknown, and even ulceration and gangrene have been attributed to its use. Because of the irritant action of the products containing the salicyl group on renal epithelium, acetylsalicylic acid is contraindicated in nephritis. Other persons especially susceptible to undesirable effects of the drug are drunkards and persons with diabetes. In the latter groups, adverse effects show a special relation to the nervous system.

Now comes a report¹ from the London *Lancet* indicating that a surprising number of deaths reported in England are due to this product, much out of proportion to the experience in the United States. According to this source, in England and Wales in 1938 the number of deaths due to poison was reported to be 735, of which 591 were suicides, ninety-two accidental and the remaining doubtful. The agent responsible for forty-three of the suicides, for eight of the accidental and for fourteen of the doubtful group of deaths was said to be aspirin; thus aspirin was reported as the cause of death in sixty-five of 735 fatal poisonings. In 1937 about the same number of deaths from poison occurred in this area, with aspirin listed as the responsible agent in sixty-one cases. In 1936 the number recorded was about half of the number in 1938, which would indicate that aspirin caused about 150 deaths in three years in England and Wales alone. The *Lancet* considers it "curious" that a drug which caused sixty-five reported deaths in one year is not classified as a poison. An antidote is not known for the treatment of cases of acute poisoning. Therapeutic agents which may be harmful in excess dosage have recently been subjected in Great Britain and in some areas in this country to certain restrictions to prevent excess sale to the public. Perhaps further attention should be given to acetylsalicylic acid (aspirin) if it is capable of causing as many deaths as have been reported in Great Britain.

Another member of the salicylic acid family which does not have altogether the same side reactions is methyl salicylate, well known commercially as oil of wintergreen. Approximately two years ago THE JOURNAL published an article on methyl salicylate poisoning in which Baxter, Hartwell and Reck² reported two deaths in children following the accidental swallowing of oil of wintergreen. The authors also referred to an article in the *Archives of Pediatrics* wherein twenty-eight cases of methyl salicylate poisoning were reviewed by Lawson and Kaiser,³ who added another case of death following the use of methyl salicylate as a counter-irritant. In the twenty-eight cases reported by Lawson and Kaiser there were ten recoveries and eighteen deaths. It is also interesting to note that, in the report of the Registrar General in Great Britain on Poisoning, methyl salicylate was shown to be responsible for three deaths in 1938, four in 1937 and four in 1936. Because of two recent deaths of children in Canada the Canadian Council of Health⁴ is considering classifying methyl salicylate as a poison. The mortality among the children has been as high as 60 per cent, even though only a small quantity has been taken. Evidently much more attention should be given to the toxicity of these rather common products which are used both in the home and in the practice of medicine.

Current Comment

MILITARY PREPAREDNESS

Elsewhere in this issue under the heading of Military Preparedness appear the minutes of the special session of the Committee on Medical Preparedness of the American Medical Association which called in Chicago a conference of all the chairmen representing the different state organizations for military preparedness. There appear also the minutes of the meeting of the committee itself, held the same day. In attendance also were representatives of the United States Army and Navy Medical Corps, the United States Public Health Service and the Selective Service organization. The information supplied was of the utmost importance in developing plans for the organization of the medical profession in relationship to mobilization of men for military service. Every physician should read carefully these minutes in order that he may be aware of the answers to many of the questions which are now pouring into the headquarters office. Every physician is anxious to do his part. Every physician is likely to be asked also as to exemption of various groups of the population, physical examinations and similar subjects. Most of the answers will be found in the material published in this issue. If not, at least there will be an indication as to the proper agency to be consulted for a proper answer.

THE EFFECT OF INDUSTRIALIZATION ON MORTALITY FROM TUBERCULOSIS

In a series of studies of mortality from tuberculosis and industrialization with special reference to the United States, Wolff¹ has presented statistical data obtained from many sources. The disease continues to retain its important place as a cause of death in spite of a remarkable decline. This is due, Wolff believes, to two causes: first, the prevalence of tuberculosis in persons in the prime of life; second, the fact that, as a chronic infectious disease, tuberculosis becomes active at any time when environmental conditions become unfavorable for large groups of people. Such was the experience of the World War in all those countries directly or indirectly implicated in war distress. Surprisingly, however, increasing industrialization has been accompanied by a decline in mortality from tuberculosis, probably because of the general improvement in standards of living for the bulk of the people brought about by industrialization. Density of population itself furthermore does not determine the mortality from tuberculosis but there is some other causal factor probably connected with crowding and social environment. It is therefore rational, Wolff believes, to aim preventive measures largely at improving social environment. For the time being at least the level of mortality from tuberculosis may be considered an index of hygienic and social culture. By this standard the United States ranks first among the world states even when the high mortality of the Negroes is included.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

CONFERENCE ON MEDICAL PREPAREDNESS

Held at American Medical Association Headquarters,
Sept. 20, 1940

Because of the illness of Dr. Irvin Abell, chairman of the Committee on Medical Preparedness, Dr. James E. Paullin was elected to preside. A telegram from Dr. Abell said: "Am distressed in not being able to be present today at what I regard as an extremely important meeting. Since the A. M. A. has voluntarily assumed the responsibility for surveying the qualifications and availability of the medical personnel of the country, nothing should be allowed to interfere with the successful and prompt fulfillment of this self-imposed obligation. In the degree in which we succeed we shall be judged, and our responsibility to the American Medical Association demands 100 per cent fulfillment. Such states as are in arrears should be made to realize their duty and, if necessary, change in committee personnel made to give some assurance of discharge and fulfillment of duties assigned. With assurance of my hearty cooperation in all that you do, Sincerely, Irvin Abell."

The Coordinating Committee

Dr. Olin West, Secretary of the American Medical Association, reported the text of the executive order by the President creating the Coordinating Committee as described in THE JOURNAL last week.

The Medical Examining Function under Selective Service

Col. Charles B. Spruit gave the available information describing the work of the physicians under the Selective Service Act. This paper was published in full in THE JOURNAL last week.

Dr. Samuel J. Kopetzky, New York, stated that the medical profession had been completely organized for service in the selection of young men for training under the Selective Service Act. The governor of the state had conferred with him as chairman of the Preparedness Committee of the American Medical Association in New York. The state had been divided into eight police districts with main headquarters in Albany and separate headquarters in New York City, the mayor of New York City being in charge of these activities and the rest of the activities of the state under the direction of the Adjutant General in Albany. Two nominees were selected for each draft board of the state, and the governor selected a physician for each 30,000 of the population in the state to serve on the local draft board. Similar arrangements were made for the city after conference with the five county medical societies in Greater New York. Arrangements were also made to set up medical advisory boards to pass on appeals from decisions of the physicians of the local draft boards. Each medical advisory board contains a surgeon, an internist, an ophthalmologist, an otolaryngologist, a psychiatrist, an orthopedist, a roentgenologist and a dentist. The mayor and the governor of New York also requested lists of physicians with a broad, communal point of view to serve with draft boards as members of the board rather than as physicians. Contact was made with the state dental association and with the state pharmaceutical association, so as to provide the necessary members of the boards from these professions.

Function of Induction Boards

Col. Albert G. Love, United States Army Medical Corps, said that registrants under the Selective Service would first be passed on by the members of the board before they were referred to the physician. In 1917 one man out of every five or six exam-

ined was unable to go because of some economic or matrimonial reason. Thus a tremendous amount of unnecessary work was placed on the shoulders of the doctors. It is proposed on this occasion to have the man passed for all other reasons before submitting to the medical examination. A different plan would involve the examination of 16,500,000 men instead of the examination of 4,000,000. Every effort is being made to examine the man as closely as possible to his home so that he will be away from his home and job or position as short a time as possible. There will be 100 induction boards to make final examinations of registrants before they are sent to cantonments and camps. Selection and organization of these boards will be determined by the corps area commander. There will be one or more of these boards for every state, depending on the population. On each of these boards there will be one orthopedist, one general surgeon, three internists, two ophthalmologists, one otolaryngologist, one neuropsychiatrist, one clinical pathologist and one dentist.

The United States Public Health Service has taken over the work of collecting and making serologic examinations. X-ray examinations of the chest will not be made at these examining points for all men but will be made only as required in order to determine definitely whether a man is physically fit. Only such laboratory work will be done as the examination of sputum and urine. If more technical laboratory work is required, it will be delegated to local medical facilities. After the man is inducted and brought into camp a general x-ray examination of the chest of each man will be made, with the preparation of two permanent films. A hundred x-ray machines for the taking of such films have been ordered and will be delivered within the next six months.

Colonel Love stated that there are approximately 15,000 reserve officers now in the Medical Reserve Corps. The Army will require 8,000 physicians in addition to those now in the Army Medical Corps and those in the National Guard. If the 8,000 are taken from the Reserve Corps, it will be necessary to rebuild the Reserve Corps. In the setting up of the induction boards it is proposed to use civilian specialists as well as reserve officers. The Committee on Medical Preparedness will be associated with the development of the necessary personnel.

Medical Officers for the Navy

Capt. D. G. Sutton, United States Navy Medical Corps, pointed out that the Navy was not involved in any way with the problem of Selective Service at this time. Should the Navy become involved, the physical standards will be about the same as those set forth by the Army. All naval recruits are centralized in areas known as Naval Training Stations, of which there are eight or ten throughout the United States. The maximum number of men required by the Navy is about 500,000. He asked particularly that interest be stimulated in the Naval Reserve Corps as far as physicians are concerned. There are now approximately 1,100 vacancies in the various categories in the Naval Reserve Corps, that is of commissioned medical officers, and about 208 vacancies in the regular service. The Navy prefers the younger men who are recent graduates from class A medical schools.

Instead of planning for the large x-ray film of the chest, the Navy is using the small 25 mm. film.

DISCUSSION

The subject of the selection of physicians for the induction boards was discussed by Drs. Holman Taylor, Texas; W. C. Dixon, Tennessee; Stanley H. Osborn, Connecticut; F. X. McGovern, District of Columbia; John F. Sharp, Utah, and W. R. Brooksher, Arkansas.

Status of Physicians on Draft Boards

In reply to questions raised in this discussion, Colonel Spruit said that a member of the Selective Service Board will be a government official of the Selective Service. Physicians on the boards will not be paid. Colonel Spruit quoted the policy of Selective Service:

"There is a strong feeling in Congress and throughout the nation that, inasmuch as men are being called to military service at great personal sacrifice, Selective Service officials should be men willing to make an important sacrifice by contributing voluntary service, and that a process based on the devotion to the national interest should not deteriorate into a job-holding organization.

"It appears very probable, therefore, that no compensation will be provided for members of local boards, boards of appeal, medical advisory boards, examining physicians, additional examining physicians or other similar officials. Clerical employees will unquestionably be paid and will be thoroughly competent in order to free officials from petty clerical routine and leave them free to devote their time to their important responsibilities."

Provisions have been made to furnish supplies utilized and required in physicians' examinations in the Selective Service process and to pay for those procedures necessary for the determination of physical fitness, such as laboratory or x-ray examinations. Colonel Spruit requested the Committee on Medical Preparedness to establish a fair list of prices for technical examinations, which will be paid for from government funds after the due amount of paper work has been accomplished.

Colonel Spruit indicated that the fall quota for the Selective Service would be about 400,000 men, divided equally between 6,500 local examining boards, which would require about sixty men to be selected by each board. Applying the percentage of rejections, about ninety men would come before the physicians of the local board for physical examination. Since, however, the examinations are to be spread over a period of from three to four months, the total requirement of examination for each local board would be between twenty and thirty men a month.

The policy has been adopted that only doctors of medicine will be utilized in carrying out the medical functions of the Selective Service.

No plans have been made for taking men with correctable defects into the Army. Colonel Spruit said it would be a broad and desirable humanitarian procedure if the Army were able to take in the defectives of the nation secured by the draft and fix them up so that they could go back into civil life as good sound men. However, the purpose of the act is to get men to do twelve months of training and service, after which time these men go into the reserve for a period of years. The Army wants men who are immediately capable of undertaking full military service and not those who are inducted and then sent to hospitals for treatment before they can begin training. Men with correctable defects may be deferred by the local board, subject to a voluntary correction of the defects if the young man cares to have such correction made.

It is contemplated that the physicians who are members of induction boards may be compelled to travel in carrying out their services.

The Reserve Corps

Colonel Love, United States Army Medical Corps, pointed out that the Adjutant General, at the request of the Surgeon General, has sent out to every corps area commander who works through the corps area surgeon a request to send to every reserve officer a questionnaire in which he is asked whether he desires to accept military service at this time. If he cannot accept military service at this time, he is asked to put down the reason for his refusal. The army requires definite information as to the men who may be available for military service with the least possible disruption of the civilian medical services as far as teaching and hospitals are concerned. Doctors are required for 1,400,000 men who will be in training. When physicians are called under the Selective Service Act, they will have special status. Any man who is eligible for Selective Service may apply now for a commission in the Medical Officers' Reserve Corps. If he does not apply for a

commission and later is selected for service and taken into the Army, he will then be given an opportunity to qualify for a commission. He will, however, avoid registration under the Selective Service Act if he applies at once for a commission in the reserve corps.

The subject of examinations of interns, residents and medical students was further discussed by Dr. F. L. Smith, Minnesota; Dr. James E. Paullin, Georgia, and Dr. Harvey B. Stone, Maryland. Instructions have been sent, said Colonel Love, to the effect that an intern who has not completed one year of service is not to be considered eligible for active duty. Moreover, second year interns have been placed on a low priority list and are not to be disturbed if this can possibly be avoided.

Physicians on Induction Boards

In reply to a question, Colonel Love stated that physicians who are serving on induction boards, with the exception of the officer in charge of the board, will be on temporary duty. Reserve officers who are available will be called under a temporary duty status. Civilian physicians will be on a per diem basis and will be used as long as their services are required. Civilian physicians will be without military status. It is planned to utilize the services of those who, on account either of age or of physical deformities or because of reasons affecting their civil life, cannot go to military camp but are willing to engage in this type of service and thus do their part in the field of national defense.

The work of the physicians on the Selective Service Board, as developed in Indiana, was described by Dr. Charles R. Bird.

Arrangements were made to send to the headquarters of the American Medical Association complete lists of the names of all physicians serving on Selective Service local boards and advisory boards. Dr. Olin West pointed out also the need for supplying the headquarters office a complete list of all medical reserve officers in each state. Further discussion was supplied by Dr. Hugh H. Trout, Virginia, who requested information as to the manner in which the list of questionnaires was to be made complete. Dr. Arthur T. McCormack, Kentucky, described the activities carried on in that state, which now has the record of having secured the greatest number of returns. Dr. Holman Taylor, Texas, discussed the recording and status of physicians associated with the National Guard.

Exemptions of Medical Students, Interns and Residents

Dr. Olin West pointed out that many letters had been received in the headquarters office from interns, residents and medical students, as well as from faculties of medical schools, inquiring as to the status of these groups under the Selective Service law. Dr. Morris Fishbein asked as to the status of interns under the Selective Service and as to whether or not they would be given an opportunity to qualify for a commission in the Medical Reserve Corps. It was pointed out that the Selective Service Act exempts young men in universities in training for degrees in science and that many medical schools do not award a diploma until after the internship is completed. It was pointed out also that the certifying boards for the various specialties would have to arrange in some manner to provide for the resident who had completed one or two years of his residency or fellowship and who was called to military service. In response Colonel Spruit said:

"I shall have to descend to the status of a guardhouse lawyer, since this is now a matter of the interpretation of the law. Let me read you a brief description of what the law says. Now the law uses two terms: one of them is the word 'exemption,' which means to clear out; the other is the word 'deferment,' which means to put off. And so with those two barnyard definitions we will proceed.

"The first exemption that is open or that will be conferred upon members of the medical profession is an exemption from registration. Obviously, if you don't get your name on the book, they can't find you. So if you are not registered, if you are exempt from registration, you will not be called. And the exemptions from registration comprise the warrant officers and enlisted men of the Regular Army, Navy, Marine Corps, Coast Guard, Public Health Service, the federally recognized active National Guard, the organized reserve of the Regular Army,

the enlisted men in the Naval Reserve, the Marine Corps reserves, cadets of the U. S. Military and Naval academies, cadets in the Coast Guard academies or men who are accepted for admission thereto, and cadets of the advanced corps of the R. O. T. C. in the Army or in the Navy.

"Now, we have twenty-three medical R. O. T. C. units in the country, which means that those men in there who are in their junior and senior years will be exempt from registration. All students presently entered on college courses leading to a degree in the arts or sciences will be deferred until July 1, 1941, which means that all students who are entering courses leading to a degree are deferred for this year. However, they must register. If I understand the law correctly, then the R. O. T. C. medical students don't have to register, the assumption being that we are going to get them in the reserve corps at graduation.

"When we come over to this question of deferments, we come from a definite classification to a lot of general terms. Let me read you the statement in regard to no deferments. The law says: 'There will be no deferments made in the case of any individual except on the basis of the status of that individual, and further that no deferment shall be made of individuals by occupational groups or of groups of individuals in any plant or institution.' In other words, there will be no blanket deferments except those authorized by the law.

"It will thus be seen that the deferment of any individual whose exemption or deferment is not specifically provided by law will be decided by local boards on the merits of the case and the demonstration of the necessity for deferment. It is believed that such necessity can be demonstrated for residents and interns in hospitals, for key technical personnel in hospitals and laboratories and for officials in state, county and local health departments, and similar participants in matters of the public health.' That is a very broad provision upon which I shall not attempt to elucidate at this time.

"Furthermore, men may be granted exemption under the judgment of the local boards who are found, as individuals, to be necessary in industry, agriculture or some other occupation in order to maintain national health, safety or interest."

"I feel, as every one in the room must feel, the dire necessity of providing for the continued training of medical education in the country. Those students will be deferred for another year, but each case is going to have to be settled, under the present law, on its own present merits. As far as the men in hospitals are concerned, I would like to hark back to what I said before; namely, that there are three ways in which an appeal can be made to the classification of any man: the individual himself, his employer or the government agent who is appointed to look after the interests of the government and of the community at large. So that if the man himself doesn't appeal but if the hospital in which he is an intern or a resident thinks that he is vital and can support their case, they can request an appeal."

Dr. Edgar H. Greene, Georgia, inquired as to the status of public health officials who are also members of the reserve corps. He inquired also as to the possibilities of additional R. O. T. C. units in medical schools. Colonel Spruit pointed out that authority must be gotten from the War Department for the establishment of additional R. O. T. C. units, particularly since an appropriation would be required from Congress. He felt that this was a feeble reed on which to lean for the deferment of medical students. All men who are on the active list of the organized reserves are exempt from registration; that is, any one who is in good standing and an officer in the reserve corps will not be registered. The question was further discussed by Drs. Holman Taylor, Stanley H. Osborn and Charles H. Henninger, Pennsylvania, with respect to exemptions of public health officials.

Dr. W. D. Cutter reported on the results of the questionnaires sent to medical schools asking them to furnish the classifications of the faculty with regard to those essential to the continued conduct of the school, a second group whose presence was desired but who were less necessary, and a third group of those who could readily be spared for military duty. Fifty-seven schools have already sent lists of the faculty thus classified. Others are completing the lists just as soon as members of the faculties return from their vacations.

Dr. Alexander S. Begg, Massachusetts, reported on the work of the Committee on Mobilization of the Association of American Medical Colleges. Dr. Begg analyzed the Selective Service Act as it relates to the students. He felt that under the law deferment is made possible on presentation of information to the Selective Service boards. He also discussed the question of hospitals which are not teaching hospitals but which are necessary for community health.

Serologic Tests of Selective Service Registrants

Dr. Thomas Parran said that he thought it desirable to provide opportunity for a Wassermann test to the 16,000,000 registrants, who would report at 143,000 registration booths. Men of the ages of 21 to 35 would represent 70 per cent of the active syphilis of the nation. Some 900,000 cases might be expected to be found if it was possible to make routine tests of the entire 16,000,000 men. Of the 900,000 cases with positive reactions, about 300,000 would be infectious, he said. Difficulties represented were the lack of physicians capable of supplying 143,000 registration offices with men capable of taking blood and the volume of serologic tests which would be necessary. The American Legion had offered to give help in the clerical and other necessary work and to encourage the registrants to take the tests. Dr. Parran discussed the incidence of syphilis in this age group and proposed the following plan:

"Specifically it is proposed that the collection and examination of specimens be accomplished as follows:

"1. A team of one or more doctors and nurses to be provided at each registration point and to be responsible for the collection of the specimens. Local and state health departments should be able to obtain the services of the physician and provide the nurse in cooperation with the local and state medical societies without cost to the selective draft board.

"2. The blood specimens with the identification blank properly filled out to be sent to the nearest public health laboratory where serologic tests for syphilis are performed. Such laboratories should be notified, if possible, ten days to two weeks in advance of the approximate dates of registration in order that routine serologic work may be set at a minimum during the registration.

"3. The men whose blood specimens proved to be negative by serologic test should be notified directly regarding the laboratory findings. The men who have positive or doubtful serologic tests should be directed by mail to report to the physician or clinic named on the original identification slip which was forwarded from the collection point to the state laboratory. The positive or doubtful report should be sent to the man's physician or clinic in order that the proper physical examination may be performed to supplement evidence obtained through serologic examination of the blood and necessary to confirm the diagnosis of syphilis.

"4. Individuals found to be infected with syphilis may according to circumstances arrange for treatment either from their own physician or from public clinics, of which there are approximately 2,500 at various places throughout the United States."

He stated that the plan has the approval of the Subcommittee on Venereal Diseases of the National Research Council, and it was hoped that the American Medical Association would encourage the plan through its affiliated state and county medical societies, thus securing the cooperation of the physicians.

In the discussion Dr. Samuel J. Kopetzky stated that the matter had been brought before the Medical Society of the State of New York and that it was the feeling of the council that the Selective Service Act, with its registration and its examination, is a new procedure and it would be unwise to complicate it with public health activities. Such complication would confuse the public and give newspapers and other agencies not favorable to Selective Service an opportunity to condemn the entire procedure. It was felt, however, that a serologic program could be conducted for the 400,000 men who would be accepted and inducted into service. Dr. George M. Smith, Connecticut, and Dr. Arthur T. McCormack, Kentucky, commented on the plan, the statement by Dr. McCormack ending with a recommendation for its adoption.

AFTERNOON SESSION

Resolution on the Rehabilitation of Men
Disqualified for Service

Dr. Parran of the U. S. Public Health Service presented a statement prepared by a committee of the Conference of State and Territorial Health Officers concerning the rehabilitation of men found disqualified for service by reason of physical defects. The following resolution, offered by the committee of the Conference of State and Territorial Health Officers, was read. Dr. Parran suggested that the resolution be a possible subject for future consideration by the Committee on Medical Preparedness:

Resolved, That persons who are otherwise found to be satisfactory and available for induction into the land or naval forces of the United States for training and service as provided by the Selective Service Act but who are deferred because of physical defects or ailments which are readily amenable to treatment and cure as stipulated by regulations which may be prescribed by the President may, on application to the Public Health Service, be considered and accepted for such treatment as beneficiaries of that service for the correction of such physical defects or ailments.

Relations of Committee on Medical Preparedness
to Governmental Agencies

Dr. Morris Fishbein stated that a chart is being prepared which will clearly show the relation of the various bodies and committees which have been formed, indicating also just where official power lies, where advisory power lies and which bodies are without authority. He said that, while various governmental agencies had requested the American Medical Association to aid them in mobilizing medical personnel, the Committee on Medical Preparedness appointed by the Association for that purpose has no authority to order anybody into service but can only find out if an individual wants to go into the service and furnish such names to the government. The punch card system on which the Committee on Medical Preparedness is working is of real value only if it is complete. Obviously a good job cannot be done if there is on the punch cards only 75 per cent of the doctors who are available. The very first job, therefore, Dr. Fishbein said, that lies before the state chairmen when they return home is to obtain the return of all the questionnaires of the medical preparedness committee which have been sent out to individual physicians, in order that the punch card system may be complete. This work of mobilizing medical personnel is greatly complicated by the fact that there are innumerable medical organizations in the field; for example, some of the boards in the specialties have urged that physicians be not recommended for service on any board as specialists unless they hold a certificate from the examining board. This would be most difficult to follow in some states. Other complications that were mentioned were the needs of industrial medicine, the promotion of public health activities in relation to the military emergency, and the question of medical students. The needs of the military service obviously come before every other demand.

Intensification of Medical Education

Dr. William D. Cutter said that the Council on Medical Education and Hospitals as yet has no specific plans for the intensification of medical education in relation to the Conscription Act. The Council has not met since this bill was enacted. Certain medical schools, however, have been considering the lengthening of their school year so that the course can be completed in three calendar years rather than in four. Some schools are already operating on that plan and it would be very difficult for others to adopt that plan.

Dr. Alexander S. Begg pointed out that a group interested in the venereal disease problem had sent a memorandum to all medical schools suggesting an intensive two weeks course be offered to physicians who are able to go into the service. He suggested that probably the orthopedists and various other groups might want short intensive courses given also.

Dr. Olin West brought out that various groups are attempting to exert influence in Washington in behalf of plans for the extension of what they call medical education. Indeed, a bill has been introduced in Congress designed to care for the interests of one unrecognized medical school. Certain commercial groups are trying to exert pressure in the same direction in Washington. Great pressure is being brought in behalf of

certain cult practitioners in an endeavor to have them recognized in the same way as doctors of medicine are to be recognized.

Physicians to Serve the Civilian Population

Dr. West stated that under the plan adopted by the Committee on Medical Preparedness it is provided that county medical societies shall be active in the selection of physicians whose services would be more valuable among the civilian population at home than they would be if these men were called into active military service. In some states it appears that no county committees have been appointed. Dr. West said that this matter of appointing county committees should receive prompt consideration at the hands of the state committees.

DISCUSSION

In the discussion Dr. Samuel Kopetzky said that in each county of the state of New York there is already a medical preparedness committee which places a confidential notation on every questionnaire as to the value of a physician, as to his need in the community or whether he is better suited to serve in the federal service, as a reserve officer, as a public health officer, in industrial medicine in plants, in the Home Guard or in some other category.

Dr. Roy W. Fouts of Nebraska said that the plan of appointing county committees would not work in Nebraska, as there are some counties in that state which do not have even one physician, much less a county medical society, and that the same holds true for a number of the Western states. Dr. Fouts suggested that this matter be handled in Nebraska through the councilor districts rather than on an individual county society basis.

Dr. Holman Taylor of Texas said that he was one of a committee of this kind during the last war and that they went into communities where there were doctors to spare and induced those doctors to go to other sections of the state of Texas where doctors had been sent into active military service. He raised the question whether these county society committees would actually have the authority for making such decisions as this; that is, would the higher authorities endorse the county society method of selecting those that are best qualified to serve among the civilian population.

Dr. Charles W. Maxson of Maryland read a questionnaire which one of the county chairmen in Maryland had sent out to every doctor in that county.

Capt. D. G. Sutton, U. S. Navy Medical Corps, suggested that this is a national question and comes within the purview of the new coordinating committee established by executive order. This committee, he said, could outline a definite policy that could be applied to all the states after having received from the states information that would serve as a background for determining the final action.

Colonel Love said that a careful reading of the original proposal submitted by Colonel Dunham before the House of Delegates of the American Medical Association in New York last June would clear up many of the points being raised at this time. The Surgeon General's Office has proposed to the War Department that all calls for physicians beyond those who are available in the National Guard and in the reserve corps would be supplied through the Committee on Medical Preparedness of the American Medical Association; for example, a corps area commander who requires a surgeon or internist or some other kind of doctor would transmit his call to the Committee on Medical Preparedness of the American Medical Association in Chicago. The reason for that plan is that there may be many more troops in a certain corps area than can be supplied with the number of doctors from that corps area, but when a call comes into the central committee for doctors they can say to some state that it is their turn to furnish the type or types of doctors required. The Surgeon General's Office has suggested to the Secretary of War, as well as to the Committee on Medical Preparedness, that the Surgeon General have representatives on duty with this committee in Chicago so that he may give official sanction to recommendations made by this committee, which in turn will be transmitted to the state and county medical societies. Dr. James R. Bloss of Huntington, W. Va., said it could be made a simple matter for the doctors of the country to take

care of the civilian population. In the World War he and his associate asked each new patient that came to their office "Is your doctor in the service? and if the patient said yes, his name was written in red ink in their books and any amount collected from the patient was sent to that doctor's family. When physicians who were called into service returned to the community, he said to their patients "Your own doctor is back now, go over and see him." Dr. Bloss and his associates feel that this question is a personal matter to a large extent.

Dr. Olin West again emphasized the importance of completing the organization of medical preparedness committees in the county societies, which he hopes will be perfected soon in every state. There will be some things in each local situation that will have to be carefully supervised by the state committees on medical preparedness.

Dr. F. Webb Griffith of North Carolina inquired if the states are going to get duplicates of the punch cards of the central Committee on Medical Preparedness. Dr. West replied that, in view of the great pressure of trying to get this information transferred to these cards, it was doubtful whether the committee could undertake to provide the states with duplicates at any time very soon. He pointed out that the county committee should know better than anybody else which physicians can best stay at home and who might be essential for civilian service.

Dr. F. L. Smith of Minnesota said that to date they had received back 83.5 per cent of 2,600 cards sent out to physicians in the state. It is necessary, he said, to make a personal canvas, and this was being done in Minnesota through the county societies, which with the councilors have a list of all physicians in their district. In Minnesota they have a committee comprising one member for every district so that between the representative of the military committee, the county chairman and the councilor they expect to get the information desired from every physician in the state, even if necessary to make a house to house call. Minneapolis and St. Paul are already sending their representatives to interview personally men who have not returned their cards.

Dr. J. N. Davis of Idaho asked What is an acceptable per capita need of the civilian population for physicians? Dr. Olin West said that the question is difficult to answer. Should an epidemic develop as it did in 1918, there is no way of figuring out the per capita need for physicians. In a situation of that kind and in less serious situations among the civilian population we have to meet the situation that exists, and all that one can do is to do the best without reference to per capita needs.

Dr. George H. Phelps of Wyoming said that a plan which would work in one state might not work in another state. It may be well, he said, to leave this to the discretion of the Coordinating Committee in conjunction with the Committee on Medical Preparedness to work out definite ideas which can be submitted to the various states.

Dr. Fishbein referred to Colonel Love's statement at the morning session that the immediate needs probably can be taken care of out of the reserves as long as we are not actually engaged in war. Should the government declare war, this problem could not be handled without some sort of conscription that would reach physicians and provide authority to reach those physicians who are actually needed in the service, as well as to give authority to somebody to declare just who ought to stay at home and who ought to go into active service. The time is not ripe, Dr. Fishbein said, to confer that authority on any one. Dr. Olin West emphasized that while we may not be going to decide at present just who is going to stay at home and who isn't, we ought right now to be working out a plan to provide for the civilian and the industrial needs, and to this suggestion Dr. Arthur McCormack of Kentucky agreed.

Plans to Secure Return of Physicians' Schedules

Dr. R. G. Leland, whose department in the headquarters of the American Medical Association is conducting the survey of physicians for the Committee on Medical Preparedness, pointed out again the necessity for a 100 per cent return of schedules that have been sent to physicians. No state as yet had reached that point. Various means have been used by different states to secure a complete return of schedules, but it will be necessary to exert still more ingenuity and pressure on those who are tardy in returning their schedules. These schedules are needed

even though the physician has supplied the information to the Army or Navy as members of the Officers Reserve Corps. Only by having a complete list will the Committee on Medical Preparedness be able to serve the armed forces in the best manner. Dr. Leland believes that ultimately personal visitation committees will be required in most communities to follow up those men who do not respond with their questionnaires. In their effort to complete the survey of physicians, many states have asked the committee for lists of physicians who have already returned their schedules in order that they might learn the names of those who have not returned them. The preparation of such lists entails much work, for it is necessary to check all of more than 100,000 schedules that have been returned. It is especially requested that state and county committees do not ask for such lists, as that would be especially time consuming. If there are other methods which are better than preparing a list of those who have not responded, anything that can be done to assist the states in getting a full return to their questionnaires will be gladly done.

In reply to a question from Dr. Charles R. Bird as to how soon the checking of the state lists could be had by individual states, Dr. Leland replied that it probably would take from ten days to two weeks at least to make this check. In response to the question whether they have a list made up of those who have filled out the questionnaires, the answer was yes, except in a few states in which the number of returns is less than 50 per cent.

Dr. Hugh H. Trout of Virginia said that a great deal of this work in his state had been completed with the aid of the woman's auxiliaries. The women have gone out to their doctor husbands and friends and had them turn in the necessary information.

Another plan has been adopted for states in which there are comparatively few physicians, namely the sending out directly from Association headquarters of a second request for the information desired. That has been done in seven or eight states and the response to the second request has been very satisfactory.

Colonel Spruit pointed out that the regulations on physical examinations have recently been printed by the army and that he hoped that the examining boards would read and apply them.

Dr. Stanley H. Osborn asked whether the different state chairmen can get from the Committee on Medical Preparedness a list of the physicians who would volunteer for active service. Dr. Leland replied that on request a list could be prepared of those who are willing to volunteer for service.

Relation of Committee on Medical Preparedness to Other Agencies

Colonel Love stated that the Surgeon General's Office feels that the American Medical Association should be able to speak for the medical profession and that it is the wish of that office at present to coordinate, as far as possible, the work of medical preparedness through the central Committee on Medical Preparedness appointed by the American Medical Association.

The Neuropsychiatric Problem

Dr. Parran stated that, if the methods of physical examination to be followed in the current emergency are the same as those followed in the World War, and if no more of the potential psychiatric cases are excluded than in the last war, then we can expect 2.2 per cent of all men inducted into the service to become wards of the government and to receive treatment and compensation at its hands for the next twenty years following their induction. An estimate of the cost to the government of every case of this kind, including the cost of buildings, compensation and other expenses involved to take care of them, amounts to \$30,000 per case. If the same figures apply to the men to be inducted for training in the next few months, the total cost over the next twenty-two years to the government for the probably 22,000 neuropsychiatric patients would be 660 million dollars. Dr. Parran pointed out that in the last draft, in many places, the draft boards were too willing to send to the army the problem boy, the shiftless fellow, the ne'er-do-well, and that it should be possible for the local draft boards, the medical advisory boards and finally the induction boards to give more attention to this particular problem, to which he hopes the Committee on Medical Preparedness will give further consideration.

New York's Plan to Protect the Doctor in Active Service

To protect the doctor who goes into active military service, and to make it easier for him to fulfil that obligation, New York has adopted, Dr. Kopetzky said, the "Bower plan," whereby the physician going into the service notifies his county society officers, who set up a fund in which the money collected by the substitute doctor is deposited minus a certain percentage for overhead, and that fund is administered by the county medical society. Certain hospitals also have established funds within the hospital in the same way. Thus the patients of the physician who goes in the service will be taken care of by those who remain at home and the physician or his family will get the money collected by the substitute physician, less a certain per cent for overhead. Under a tax ruling in the third tax district in New York, these funds are taxable as income and when the funds are distributed to the doctors who go into the service they must register it in their income tax returns and it is again taxed. Now what is needed is an executive ruling from the Secretary of the Treasury that such funds shall either be taxed at the source or at the time the recipient gets the money. Dr. Kopetzky requested that the Committee on Medical Preparedness take this matter up with the proper treasury official, so that it may be straightened out. In reply to a question from Dr. Charles E. Hunt of Oregon, it was said that the amount deducted for overhead in some instances is 5 per cent but that it depends entirely on the local conditions, and in the case of some of the sponsored hospitals there will be no overhead charge.

Short Intensive Training Courses

The subject of short intensive training courses for doctors who are going into active service brought forth an extensive discussion. Colonel Love said that there ought to be several short intensive courses of training and that the Committee on Medical Preparedness might coordinate them and carry those courses of training through the medical schools and hospitals. Dr. Fouts suggested that all doctors up to 50 or 55 years of age who are physically fit be given a short intensive military training course. Dr. Taylor of Texas approved the suggestion. Dr. Robert Mueller of Missouri said that in the last war the percentage of decorations which doctors received in the army was greater than that of any other similar group of officers throughout the United States forces.

Dr. Edgar H. Greene of Georgia believed that the older physicians should not be subjected to intensive physical hardships but that the young physician should. The older physician who had no military training, however, should be given a course in military affairs pertaining to the manual of the medical department and the army regulations, in order to become acquainted with the paper work; he recommended in seven districts of the state of Georgia that they set up courses to instruct interested physicians along this line.

Interns and the Reserve Corps

After conferring with Colonel Love, Dr. Cutter suggested that, as soon as orders have been issued permitting the increase in the Medical Reserve Corps, it might be advisable to notify all hospitals approved for the training of interns to inform the interns that an opportunity is given them to request commissions in the Reserve Corps with the understanding that they will be expected to complete their intern service before being called into active duty. If that plan meets the approval of the Surgeon General's Office, Dr. Cutter, in behalf of the Council on Medical Education and Hospitals, said he would gladly bring it to the attention of each one of the nearly 1,000 hospitals in the country approved for intern training.

Colonel Love, in reply to a question, stated that commissions will not be granted to applicants unless they are graduates of class A medical schools.

Certificates for Physicians Compelled to Stay at Home

Dr. Harrison Shoulders of Tennessee suggested that some sort of token or certificate be issued to physicians of military age and physically fit who had volunteered for service but were compelled by the proper authority to remain at home where their services were needed. A motion was adopted to the effect that

the Committee on Medical Preparedness design and award a badge for those physicians referred to who cannot enter the active military service.

Lists of Local Examining Boards

In reply to a previous question concerning tentative lists of men assigned to local examining boards, Dr. Greene said that all one has to do to get these lists is to go to the adjutant general's office in his state and find out there what doctors have been selected for these local boards, as a mobilization plan has already been set up for several months in the states. These lists, therefore, can easily be prepared and sent in to the Committee on Medical Preparedness in Chicago.

Brief Conferences of State Chairmen

After announcements from various state chairman of requests for brief conferences with the other state chairmen in their corps areas immediately following this meeting, and that the Committee on Medical Preparedness would hold an official meeting at 6:30 p. m., the conference meeting was adjourned.

COMMITTEE ON MEDICAL PREPAREDNESS

Report of Session, Chicago, Sept. 20, 1940

Present at the session of the Committee on Medical Preparedness of the American Medical Association, held in Chicago, September 20, were:

Dr. James E. Paullin, Acting Chairman	Dr. Arthur W. Booth
Dr. Charles A. Dukes	Dr. Olin West
Dr. Roy W. Fouts	Dr. Morris Fishbein
Dr. John H. O'Shea	Dr. R. G. Leland
Dr. Stanley H. Osborn	Dr. E. L. Henderson
Dr. Walter G. Phippen	Dr. R. L. Sensenich
Dr. Fred W. Rankin	Dr. Thomas S. Cullen
Dr. Harvey B. Stone	Colonel Albert G. Love
Dr. Sam E. Thompson	Dr. H. H. Shoulders
	Dr. James R. Bloss

Dr. Paullin discussed the manner in which physicians would be selected for the induction boards. Dr. Fishbein indicated the necessity for having exact names for each of the various committees of the boards to be appointed. It was agreed that Medical Advisory Board would be the name adopted for the physicians appointed in the states to act as appeal boards from local draft decisions and that the board appointed by the Army to give the physical examinations for conscripted men before entrance into military service would be known as the Medical Induction Board. It was pointed out that it was quite possible for a physician to serve on the appeal board, which is the body appointed to act as a legal board in passing on appeals from decisions of local draft boards, exactly as a physician may also be a member of a local draft board in a capacity as a citizen rather than in a medical capacity.

Colonel Love pointed out that in some instances induction boards might travel to sparsely populated areas to conduct physical examinations rather than to have the men who were conscripted sent to the center where the induction board would hold its sessions.

COMPENSATION FOR MEDICAL SERVICES

Extended discussion brought the conclusion that physicians would volunteer their services for local boards and medical advisory boards. Colonel Love explained that the specialists who would serve on induction boards would be paid as being in the military service. By vote the conference recommended that physicians volunteer their services to local and medical advisory boards. It was also voted that a subcommittee be appointed to consider the amounts and charges to be made for special

laboratory services for local and medical advisory boards in the field of radiology and clinical pathology.

Action was also taken to the effect that a two thirds vote of the committee in case of mail vote would be considered as constituting approval.

The compensation for members of medical induction boards was recommended to be that of the rank of major, with allowances.

MECHANISM OF APPOINTMENT OF MEMBERS OF INDUCTION BOARDS

The committee recommended that members of induction boards be appointed by nomination from the state chairmen to the headquarters of the Committee on Medical Preparedness, which would then supply acceptable lists to the corps area commanders. Dr. Leland presented the system of tabulation by which men acceptable in the various specialties will be listed so as to be available for this purpose.

CORRECTION OF DEFECTS IN MEN REJECTED FOR PHYSICAL REASONS

It was moved and approved that the committee recommend to the Selective Service draft boards that registrants rejected on account of physical defects be given a statement on request as to the nature of the defects for which they were rejected.

INCOME TAX

On motion and approval it was recommended to the Treasury Department that the resolution of Dr. Kopetzky with regard to income tax be approved and that the taxes on such funds be allocated either at their source or to the individual but not to both.

SEROLOGIC EXAMINATION OF REGISTRANTS

After extended discussion it was moved and approved that the committee defer any action on the question of serologic tests for registrants. It was also moved and approved that a serologic test be a part of the examinations to be made by induction boards.

THE STATUS OF NEGRO PHYSICIANS

The secretary presented a communication received from the committee representing the National Medical Association as to the status of Negro physicians in medical military preparedness and requesting membership of Negro physicians on the Committee on Medical Preparedness. The committee endorsed a reply of the Board of Trustees to the effect that the Committee on Medical Preparedness had been appointed by the House of Delegates and that it would be impossible to change the membership of that committee until a further action of the House of Delegates became possible.

INSPECTION OF SCHOOLS OF PHYSICAL THERAPY

The secretary presented a request from the Committee on Physical Therapy of the National Research Council that the Council on Medical Education and Hospitals of the American Medical Association inspect schools of physical therapy for their ability to provide physical therapy technicians and physicians specializing in physical therapy for military needs. It was moved that the communication be received and referred to the Council on Medical Education and Hospitals with approval.

PREPARATION OF WAR MANUALS

The secretary presented a communication relative to the preparation of manuals dealing with medical subjects for the use of the medical military services. This

communication was referred to the Committee on Information of the National Research Council, which has these matters in hand.

OFFICIAL STATUS OF THE COMMITTEE ON MEDICAL PREPAREDNESS

After discussion it was approved that the Executive Committee of the Committee on Medical Preparedness be authorized to present to the Coordinating Committee on Medical Preparedness of the Council on National Defense the needs of the Committee on Medical Preparedness as far as concerns any budget and the establishment of suitable status for the committee in relation to the Coordinating Committee.

AMERICAN PHYSICIANS VOLUNTEERING FOR SERVICES IN THE UNITED KINGDOM

A communication was presented by the secretary from the secretary of the British embassy requesting that announcement be made to the effect that "The registration and selection of American volunteer doctors for duty in the Emergency Medical Service in the United Kingdom will in the future be undertaken by the American Hospital in Britain, Limited, 321 East Forty-Second Street, New York City. Dr. Foster Kennedy, together with an advisory board of this organization, will be in direct communication with the Ministry of Health in England concerning all these matters."

LECTURES ON MEDICAL PREPAREDNESS

The speakers for current lectures in the course on medical preparedness presented by the Philadelphia County Medical Society have been announced as follows:

Lieut. Col. Arthur P. Hitchens, Medical Corps, U. S. Army, professor of military science and tactics, Concentrations of Civilian Personnel—Epidemiologic Aspects, Contagious and Venereal Disease Problems, October 3.

Edwin W. Adams, associate superintendent of schools, Expected Psychiatric Problems in a Mobilization, October 10.

Dr. William Bates, Surgery of War as Contrasted with Industrial Surgery, and Dr. James B. Mason, Mechanism of Wound Production by Projectiles, October 17.

Station WDAS in Philadelphia is broadcasting a part of each of these lectures on Thursday afternoons.

THE BRITISH NEED SURGICAL SUPPLIES

The Medical and Surgical Supply Committee has issued an appeal to doctors to join a nationwide campaign for medical and surgical supplies to equip emergency stations and field hospitals to relieve the present medical crisis in England. The British Red Cross has cabled that it urgently requires surgical instruments of all kinds and five tons of plain lint and two tons of boric lint. The Medical and Surgical Supply Committee, which is sponsored by a group of physicians, acknowledges donations of medical supplies from several large pharmaceutical and instrument companies; also some gifts for funds from various parts of the country. The committee hopes to equip 500 emergency stations, as well as field hospitals. A first aid post can be equipped for \$500. Contributions should be made out to the treasurer of the Medical and Surgical Supply Committee, Arthur Kunzinger, of the Chase National Bank. The headquarters office of the committee is at 420 Lexington Avenue, New York City.

ORGANIZATION SECTION

OFFICIAL NOTES

ADDRESSES BY OFFICIAL STAFF

DR. PAUL C. BARTON:

- October 22—Southwest Missouri State Teachers College, Springfield, Mo.
- October 22—Woman's Auxiliary to the Greene County Medical Society, Springfield, Mo.

DR. W. W. BAUER:

- October 5—County School Teachers, La Porte, Ind.
- October 6—Health Education Institute, American Public Health Association, Detroit.
- October 8—American Public Health Association, Detroit.
- October 10—Northeast Lions' Club, Detroit.
- October 11—Joliet Woman's Club, Joliet, Ill.
- October 17—West Virginia State Nurses Association, Clarksburg.
- October 27—Academy of Medicine and the Monroe County Medical Society, Rochester, N. Y.
- October 29—Indiana State Medical Society, Woman's Auxiliary, French Lick, Ind.

DR. MORRIS FISHBEIN:

- October 4—Medical Faculty University of Minnesota, Minneapolis.
- October 7—Military Training Unit, University of Minnesota, Mayo Foundation, Rochester, Minn.
- October 10—University of Nebraska, Lincoln.

- October 24—Inauguration of new president, Ohio State University, Columbus.

DR. EDWIN P. JORDAN:

- October 11—Will-Grundy County Medical Society, Joliet, Ill.
- October 23—American College of Surgeons and American Association of Medical Record Librarians, Chicago.

DR. FRANK H. LAHEY:

- October 9—Middlesex South District Medical Society, Cambridge, Mass.
- October 18—Inter-State Postgraduate Assembly, Cleveland.
- October 21—American College of Surgeons, Chicago.
- October 30—Indiana State Medical Society, French Lick, Ind.

DR. PAUL A. TESCHNER:

- October 11—Grant Hospital, Chicago.
- October 14—University of Illinois, Chicago.
- October 16—Methodist Church, Lombard, Ill.
- October 31—Men's Bible Class, Austin Methodist Episcopal Church, Chicago.

DR. NATHAN B. VAN ETEN:

- October 7—Wayne County Medical Society, Detroit.
- October 16—Inter-State Postgraduate Assembly, Cleveland.
- October 20—The Cathedral at Boston.
- October 22—Bronx County Medical Society, New York.
- October 28—Oklahoma Medical Association, Oklahoma City.

MEDICAL LEGISLATION

MEDICAL BILLS IN CONGRESS

Changes in Status.—H. R. 960, proposing to extend the classified executive civil service of the United States, has passed the Senate, with amendments. Senator Hatch, New Mexico, submitted the following amendment, which was adopted by the Senate: "In appointing, or fixing requirements with respect to the appointment of, persons to any civil position in the government service no officer or employee of any executive department, independent establishment or agency (including government-owned, government-controlled corporations) of the United States shall discriminate against any applicant or deny to any applicant the privilege of taking any competitive examination held for the purpose of determining the qualifications of applicants for such position, because such applicant (1) has not been graduated from a particular school; (2) has not been graduated from a school which has been approved or accredited, or assigned a particular rating or classification, by any association, organization, or group; or (3) is not a member of any professional, technical, or other society or association." This bill will be further considered by a conference committee, composed of conferees on the part of the House and Senate. The Hatch amendment, if it remains in the bill, will open the way for the appointment of graduates of unapproved medical schools to any civil position in the government service. H. R. 6450 has been reported to the Senate, proposing to establish certain rights for combat veterans of wars of the United States. The bill provides, in part, that where a veteran is shown to have been engaged in combat with an enemy of the United States, or during service in some war, campaign or expedition, to have been

subjected to other arduous conditions of military or naval service, such disability as can reasonably be considered to have been due to or aggravated by the conditions of all of his active military or naval service shall be determined to be directly due to or aggravated by such service in line of duty, unless the contrary is shown by clear and unmistakable evidence. S. 4224 has passed the Senate, providing that in time of war or during an emergency declared by the President or by Congress the Secretary of War may, in his discretion, dispense with any of the examinations for promotion in the Regular Army of officers of the Medical, Dental and Veterinary Corps, except those relating to physical examinations.

Bill Introduced.—S. 4371, introduced by Senator Schwelbach, Washington, proposes that the United States Public Health Service shall provide for the care and relief of sick and disabled persons (1) employed on board any registered, enrolled or licensed vessel of the United States in the performance of duties of a workshop character or (2) employed or engaged in commercial fishing on board any such vessel or on board any boat operating from any such vessel as a base.

DISTRICT OF COLUMBIA

Bill Introduced.—S. 4376, introduced by Senator Byrd, Virginia, provides that, notwithstanding any limitation relating to the time within which an application for a license must be filed, the Commission on Licensure to Practice the Healing Art in the District of Columbia is directed to issue a license to practice chiropractic to Lou Davis on condition that he shall be found by the commission to be otherwise qualified to practice under the provisions of the healing arts practice act.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

CALIFORNIA

Plague Infection.—According to *Public Health Reports*, plague infection was proved in a pool of 129 fleas from fifteen ground squirrels (*C. fisheri*) submitted to the laboratory on July 15 from Arrowhead Dump, 1 mile east of Lake Arrowhead, San Bernardino County.

Society News.—The Los Angeles Society of Ophthalmology and Otolaryngology was addressed, September 23, by Drs. George L. Kilgore, San Diego, on "Repair of Corneal Scar"; John N. N. Osburn, Los Angeles, "Fifteen Years' Experience with Intra-Ocular Foreign Bodies," and Lieut. Thomas L. Allman, U. S. Navy, "Physical Requirements for Naval Aviation."—The Los Angeles Cancer Society was addressed, September 30, by Drs. Robert S. Stone and John H. Lawrence, San Francisco, on "Neutrons in the Treatment of Cancer" and "Artificial Radioactive Substances in Relation to Clinical Medicine," respectively. Paul C. Aebersold, Berkeley, spoke on "Modern Nuclear Physics and Cancer Therapy."—Dr. Robert E. Wyers presented a "Study of 260 Cases of Mongolism with Special Reference to Congenital Heart Lesions" before the Los Angeles Society of Neurology and Psychiatry, September 18, and Dr. David L. Reeves, "Amyotonia Congenita of Oppenheim: Report of Case with Autopsy."—Dr. Karl A. Menninger, Topeka, Kan., discussed "Eye and the Flying Dutchman: A Psychiatric Study of a Certain Aspect of the Relations Between Men and Women" before the Hollywood Academy of Medicine, September 12.

DISTRICT OF COLUMBIA

Annual Scientific Assembly.—The Medical Society of the District of Columbia will conduct its annual scientific assembly at the Mayflower Hotel, Washington, October 15-17, selecting for the theme this year cardiovascular renal diseases. The following doctors will speak:

Richard Schatzki, Boston, Roentgen Diagnosis in Cardiovascular Disease.
Raymond Hussey, Baltimore, Some Interesting Electrocardiographic Interpretations.
Helen B. Taussig, Baltimore, Congenital Heart Disease.
Thomas Duckett Jones, Boston, Acute Rheumatic Carditis.
Harry H. Donnelly, Washington, Management of the Child with Inactive Rheumatic Heart Disease.
Edward F. Bland, Boston, Differential Diagnosis of Congenital and Rheumatic Heart Disease in Children.
Walter A. Bloedorn, Washington, Recognition and Treatment of the Various Forms of Pericarditis.
Wallace M. Yater, Washington, Diseases of the Aorta.
Isaac Alexander Bigger, Richmond, Va., Diagnosis and Treatment of Heart Wounds.
George Louis Weller Jr., Washington, Surgical Shock and Circulatory Failure.
Thomas S. Lee, Washington, Hypertensive Heart Disease.
William Thornwall Davis, Washington, Changes in the Fundus Oculi in Cardiovascular Disease.
Edward Weiss, Philadelphia, Renal Involvement in Hypertensive Vascular Disease.
Maurice Charles Pincoffs, Baltimore, Cardiac Aspects of Chronic Nephritis.
Joseph Earle Moore, Baltimore, Cardiovascular Syphilis.
Howard B. Sprague, Boston, Clinical and Electrocardiographic Findings in the Aging Heart.
James Edwin Wood Jr., Charlottesville, Va., Diagnosis and Treatment of Cardiac Arrhythmias.
James Alexander Lyon, Washington, Failure of the Left and Right Sides of the Heart.
Harry Gold, New York, Digitalis: Its Action and Usage.
Ralph M. LeComte, Washington, Cardiovascular Complications of Prostatic Obstruction.
Joseph B. Wolfe, Philadelphia, Recognition and Management of Cardiac Neurosis.
Harold M. Marvin, New Haven, Conn., Diagnostic Criteria of Coronary Artery Disease.
Edwin Cowles Andrus, Baltimore, Acute Coronary Thrombosis.
Arthur M. Master, New York, Role of Effort, Trauma, Work and Occupation in the Onset and Subsequent Course of Coronary Occlusion.
Irving Sherwood Wright, New York, Diagnosis and Conservative Treatment of Peripheral Vascular Diseases.
Norman E. Freeman, Philadelphia, Surgical Treatment of Peripheral Vascular Disease.
Achilles L. Tynes, captain, medical corps, U. S. Army, The Heart During Anesthesia.

The program also includes a hobby show and luncheons to be addressed by Major Gen. James C. Magee, surgeon general of the U. S. Army, and Edward M. Curran, U. S. Attorney for the District of Columbia. There will be a public meeting Wednesday evening.

GEORGIA

Society News.—The Fulton County Medical Society was addressed in Atlanta, September 19, by Drs. Hulett H. Askew and Rufus A. Askew on "Hemorrhoidectomy." Dr. Cyrus W. Strickler Jr. gave a clinical talk on "Intravenous Sodium Sulfapyridine Monohydrate in Pneumonia." The society was addressed, September 5, among others, by Drs. William R. Crowe Jr. and Gene Nardin, Atlanta, on "Hyperparathyroidism."

Annual Industrial Meeting.—The third annual meeting of Georgia Association of Industrial Surgeons was held at the Ansley Hotel, Atlanta, September 25. Among the speakers were:

Dr. McIver Woody, New York, Industrial Medicine as a Specialty.
Dr. Lloyd Noland, Birmingham, Ala., subject not announced.
Drs. Edward C. Holmblad and Kenneth L. Matson, Chicago, Gas Gangrene, Plea for Better Prophylaxis.
Dr. Cleveland D. Wheelchell, Gainesville, Chest Surgery.
Dr. Benjamin H. Minchew, Waycross, Eye Injuries in Industry.
Dr. Samuel F. Rosen, Savannah, Occupational Dermatoses.
Dr. W. Whatley Battey, Augusta, Hernia.
Dr. Frank K. Boland, Atlanta, History of Fractures.

ILLINOIS

Physicians Honored.—Drs. Eugene D. Bergeron and Aaron S. Eshbaugh, both of Kankakee, were honored at a meeting of the Kankakee County Medical Society, September 10, marking their completion of fifty years in the practice of medicine. Both physicians were accorded special recognition for service to their community and given certificates and pins from the Illinois State Medical Society. Dr. Bergeron graduated at Chicago Medical College, now Northwestern University Medical School, in 1881. Dr. Eshbaugh graduated at Hahnemann Medical College and Hospital, Chicago, in 1886. Both have been practicing in Kankakee for about forty years.

Chicago

Annual Prize of Surgical Society.—Manuscripts for the third award of the annual prize of \$250 of the Chicago Surgical Society should be submitted to the secretary not later than March 1, 1941. The prize is awarded to a young man devoting himself to surgery in Chicago, who is not a member of the Chicago Surgical Society, for meritorious work in one or both of the fields of experimental and clinical surgery. Certain qualifications must be met in the judging of the papers. Additional information may be obtained from the secretary, Dr. Michael L. Mason.

KENTUCKY

Society News.—Dr. Robert Julian Estill, Lexington, addressed the Woodford County Medical Society, Versailles, September 6, on "Diseases of the Newborn."—Dr. William B. Moore addressed the Harrison County Medical Society, Cynthiana, September 2, on "Treatment of the Failing Heart."

State Medical Election.—Dr. Elmer L. Henderson, Louisville, was named president-elect of the Kentucky State Medical Association at the annual meeting in Lexington in September, and Dr. Austin Bell, Hopkinsville, became president. Vice presidents elected were Drs. William R. Parks, Harlan; Ernest Lee Heflin, Louisville, and William E. Gary, Hopkinsville. The 1941 meeting will be in Louisville.

Personal.—Dr. Andrew B. Steele has resigned as clinical director of the Western State Hospital, Hopkinsville, to join the staff of the Indiana state welfare department, it is reported. —Dr. William G. Morgan, Cadiz, health officer of Trigg and Lyon counties, has been appointed health officer of Daviess County, with headquarters in Owensboro. He succeeds Dr. William Lee Tyler Jr., who has been part time health officer. —Dr. Jerauld A. Campbell, Niagara Falls, N. Y., has been appointed health officer of Grayson County. —Dr. Mildred E. Burton, Berea, has been appointed health officer of Owsley County.

LOUISIANA

Dr. Musser Named President of State Board of Health.—Dr. John H. Musser, professor of medicine at Tulane University of Louisiana School of Medicine, New Orleans, has been appointed president of the Louisiana State Board of Health to serve on a part time basis until January during the reorganization of the board. Dr. Musser succeeds Dr. Joseph A. O'Hara, who resigned after holding the position since 1928. The change was to be effective September 1, newspapers reported. The appointment of Dr. Robert H. Onstott, U. S. Public Health Service, as executive officer of the board was also announced. In this capacity, on a full time basis, he will act as medical consultant in the reorganization of the board.

MICHIGAN

The Business Side of Medicine.—A symposium on the business side of medicine was a feature of the seventy-fifth annual meeting of the Michigan State Medical Society, Detroit, September 24. It was arranged especially for the secretaries and office assistants of members of the state society with Dr. Allan W. McDonald, Detroit, president, Wayne County Medical Society, presiding. Dr. Paul R. Urmston, Bay City, then president-elect of the state society, gave an address of welcome. Other speakers included:

Mrs. Marjorie Euler, Topeka, Kan., The Highlights of Twenty-Five Years of Service.
Miss Maxine Robinson, Muskegon, Organizing the Medical Assistants' Society of Muskegon County.
J. D. Laux, executive director, Michigan Medical Service, Detroit, How to Bill Michigan Medical Service.
Dwight Anderson, L.L.B., New York, director, public relations bureau, Medical Society of the State of New York, What Every Woman Knows.

Postgraduate Programs.—A series of postgraduate courses for practicing physicians will soon begin throughout Michigan under the auspices of the Michigan State Medical Society, University of Michigan Medical School, Ann Arbor; Wayne University College of Medicine, Detroit; and the state department of health, Lansing. The programs will be conducted at the following places:

Ann Arbor, October 10, 17, 24, 31.
Battle Creek-Kalamazoo, jointly, October 8, 15, 22, 29.
Flint, October 9, 16, 23, 30.
Grand Rapids, October 10, 17, 24, 31.
Lansing-Jackson, jointly, October 10, 17, 24, 31.
Manistee-Traverse City-Cadillac-Petoskey, jointly, October 11, 18, 25, November 1.
Mount Clemens, October 9, 16, 23, 30.
Saginaw, October 7, 14, 21, 28.

Included among the subjects for discussion are: the newborn period; the management of labor; development of hernia; significance of albuminuria; the psychoneuroses; laboratory procedures for office practice; nasal accessory sinus diseases in the practice of medicine, and the differential diagnosis of coma.

MINNESOTA

Changes in the Medical School.—New appointments to the University of Minnesota Medical School, Minneapolis, included the following:

Lemen J. Wells, Ph.D., assistant professor of anatomy, University of Missouri School of Medicine, Columbia, as associate professor of anatomy.
Dr. Charlotte M. Gast, formerly of New Bedford, Mass., assistant professor and assistant director of a course in medical technology.
Edwin S. Fletcher Jr., Ph.D., Chicago, and Robert B. Dean, Ph.D., Rochester, N. Y., instructors in the department of physiology.

The following promotions in the medical school have also been announced:

Halvor O. Halvorson, Ph.D., professor of bacteriology.
Dr. Raymond N. Bieter, professor of pharmacology.
Dr. William A. O'Brien, professor of preventive medicine and public health and director of postgraduate medical education.
Dr. Cecil J. Watson, professor of medicine and director of the division of internal medicine.
Dr. William T. Peyton, professor of surgery and director, division of neurosurgery.
George O. Burr, Ph.D., professor of plant physiology, has in addition been appointed director of the division of physiologic chemistry.
Dr. Arthur C. Kerkhof, clinical associate professor of medicine.
Dr. Starke Hathaway, clinical psychologist and associate professor of nervous and mental diseases.
Dr. James B. Carey, clinical associate professor of medicine.
Wallace D. Armstrong, Ph.D., associate professor of physiology and director of biological research in dentistry.

NEVADA

State Medical Meeting at Las Vegas.—The thirty-seventh annual meeting of the Nevada State Medical Association will be held at Las Vegas, October 10-12, with headquarters at the Elks Club. The scientific program will include the following speakers:

Dr. Victor S. Randolph, Phoenix, Ariz., Surgical Treatment of Pulmonary Tuberculosis.
Dr. Louis E. Viko, Salt Lake City, Etiology and Treatment of Hypertension.
Dr. William Whitfield Crane, Oakland, Calif., Surgical Treatment of Hypertension.
Dr. Verne C. Hunt, Los Angeles, Surgical Management of Carcinoma of the Colon.
Dr. Kenneth S. Davis, Los Angeles, Limitation and Evaluation of the X-Ray in the Diagnosis of Disease of the Gallbladder.
Dr. Gerald Brown O'Connor, San Francisco, Immediate Management of Surface Injuries.
Dr. Roland W. Stahr, Reno, Practical Points in Pediatrics.
Dr. John C. Wilson, Los Angeles, Present Status of Treatment of Fractures of the Neck of the Femur.
Dr. Hugh T. Jones, Los Angeles, Problems Encountered in the Orthopedic Care of the Knee Joint.
Dr. A. Elmer Belt, Los Angeles, Obstructive Uropathy in Childhood.

NEW HAMPSHIRE

Dr. Lancaster Goes to Dartmouth.—Dr. Walter B. Lancaster, for many years ophthalmic surgeon at the Boston City Hospital and the Massachusetts Eye and Ear Infirmary and a member of the faculty of Harvard Medical School, Boston, has been appointed chief of staff of the Dartmouth Eye Institute at Dartmouth College, Hanover, effective November 1. Dr. Lancaster is at present lecturer in ophthalmology on the staff of the Courses for Graduates at Harvard and consulting ophthalmic surgeon at the New England Hospital for Women and Children. He is a former president of the American Ophthalmological Society, the American Academy of Ophthalmology and Otolaryngology, the New England Ophthalmological Society and the American Board of Ophthalmology and in addition holds memberships in various other scientific societies. In 1928 he was chairman of the section on ophthalmology of the American Medical Association. He was also chairman of the section on ophthalmology of the National Conference on Nomenclature of Disease. During the World War he was head of the department of ophthalmology in the aeronautical research laboratories at Mitchel Field, New York. He graduated from Harvard Medical School in 1889.

NEW YORK

Million Volt X-Ray Unit at Buffalo.—Installation of a million volt x-ray therapy unit at the State Institute for the Study of Malignant Disease, Buffalo, was recently announced. A new three story wing has been built at the institute to accommodate the new unit, the offices of the director and other business offices and in addition it provides seventy-eight beds. Memorial Hospital, New York, and St. John's Hospital, Cleveland, have similar installations. Unlike previous x-ray equipment, this weighs only about 4,000 pounds and occupies only a single room.

Personal.—Dr. Harry Beckett Lang, Brentwood, has been appointed superintendent of the Buffalo State Hospital, succeeding Dr. John A. Pritchard, who has been appointed superintendent of the St. Lawrence State Hospital, Ogdensburg. —The Wayne County Medical Society at its August meeting honored Dr. John F. Myers, Sodus, for his long years of practice. Dr. Myers graduated from Columbia University College of Physicians and Surgeons and has been a member of the Wayne County society for fifty years. He received a set of travel books as a memento.

New York City

Railway Surgeons' Meeting.—The seventeenth annual meeting of the Association of Surgeons of the New York Central System was held at the Hotel Biltmore, September 24-26. Among the speakers were Drs. William W. Herrick, "Prognostic Factors in Circulatory Disease"; Charles Gordon Heyd, "A Consideration of Mortality in Gallbladder Disease," and Kristian G. Hansson, "Indications and Limitations of Physiotherapy in Railroad Injuries."

Hospital News.—The cornerstone of a new million dollar five-story dispensary building at Kings County Hospital, Brooklyn, was laid September 25. Speakers at the ceremony included Mayor La Guardia, Drs. Walter A. Coakley, president of the medical board, and Emanuel Giddings, medical superintendent. This will be the third of a series of ten dispensaries planned by the department of hospitals for different sections of the city to relieve overcrowding and inadequate service at the city's hospitals. It was reported by the hospital department that clinic visits at Kings County Hospital had increased from 163,638 in 1933 to 358,072 in 1939. New dispensaries were opened at Greenpoint Hospital, Brooklyn, in 1937 and on Welfare Island August 1 of this year.

OHIO

Society News.—Dr. Charles T. Way, Cleveland, addressed the Portage County Medical Society, Kent, September 5, on diseases of the kidney.—Dr. Gilson C. Engel, Philadelphia, addressed the Stark County Medical Society, Canton, September 11, on "Diagnosis of Intra-Abdominal Conditions."

Professor Waite Retires.—Frederick C. Waite, Ph.D., professor of histology and embryology at Western Reserve University School of Medicine since 1906 and in the dental school since 1915, has retired, having reached the age of 70. Dr. Waite took his undergraduate work and a master's degree at Western Reserve and his doctorate at Harvard University in 1898. He was appointed to the faculty of Western Reserve in 1901 as assistant professor of histology and embryology. The teaching of histology and embryology has now been made an integral part of the department of anatomy under the direc-

tion of Dr. Normand L. Hoerr. Samuel W. Chase, Ph.D., will continue the teaching of dental histology; he has had charge of this course for several years.

PENNSYLVANIA

Society News.—Dr. Garfield G. Duncan, Philadelphia, will present a "Practical Discussion of Diabetes for the General Practitioner" before the Dauphin County Medical Society, Harrisburg, October 8.

Philadelphia

Lectures at the College of Physicians.—The College of Physicians of Philadelphia opened its 1940-1941 series of scientific lectures, September 25, with an address by Dr. George W. Corner, Baltimore, on "Physiological Basis of Corpus Luteum Therapy," the Nathan Lewis Hatfield Lecture. Dr. John F. Fulton, New Haven, Conn., will deliver the S. Weir Mitchell Oration, November 6, on "Neurology and War," and Dr. Allen O. Whipple, New York, the Thomas Dent Mütter Lecture, December 4, on "Recent Studies in the Circulation of the Portal Bed and of the Spleen in Relation to Splenomegaly." Three lectures for the public have been arranged as follows:

- Dr. Chevalier Jackson, The Bronchoscope, November 15.
- Dr. Hubley R. Owen, Activities of the Department of Public Health, with Plans for the Future, Jan. 24, 1941.
- Dr. Richard A. Kern, Allergy and You, April 18, 1941.

Pittsburgh

Society News.—At the first fall meeting of the Allegheny County Medical Society, September 17, the speakers were Drs. Clifford Lee Wilmoth on "Abscess in and About the Liver"; Paul Gross, Franklin B. Cooper and Alfred F. Knoll, "Progress in Chemotherapy"; Louis H. Landay, "Treating the Allergic Patient," and William Shapera, "Dilantin Therapy in Certain Nervous Disorders."

TEXAS

Society News.—The fall meeting of the Texas Surgical Society will be held at the Rice Hotel, Houston, October 7-8, with Drs. Alfred W. Adson, Rochester, Minn., and Maxwell Harbin, Cleveland, as guest speakers.—Drs. James W. Ward and William P. Phillips, Greenville, addressed the Hunt-Rockwall-Rains County Medical Society, Greenville, September 10, on diseases of the eye and surgical treatment of acute diseases of the abdomen, respectively.—At a meeting of the Dallas County Medical Society, September 12, the speakers were Drs. Charles A. Ault Jr. on "Sarcoma of the Heart"; Elizabeth C. Williams, "Orthoptics as Related to General Medicine," and Donald G. Kilgore, "Coccydynia."

District Meeting in Texarkana.—The Northeast Texas District Medical Society will meet in Texarkana, October 8. Among the speakers will be:

- Dr. Joseph F. McVeigh, Fort Worth, Some Observations on Malaria and Its Treatment.
- Dr. Calvin R. Hannah, Dallas, Early Diagnosis of Pregnancy.
- Dr. Walter G. Reddick, Dallas, The Use of Sulfanilamide Derivatives in Acute Infections.
- Dr. Robert K. Womack, Longview, Practical Points in the Treatment of Gonorrhea in the Male.

Dr. Holman Taylor, Fort Worth, secretary of the State Medical Association of Texas, addressed a luncheon meeting on "Medical Preparedness" and Dr. Preston Hunt, Texarkana, president of the state association, also delivered an address.

VERMONT

State Medical Meeting in Rutland.—The one hundred and twenty-sixth annual meeting of the Vermont State Medical Society will be held at the Hotel Berwick, Rutland, October 10-11, under the presidency of Dr. Clarence F. Ball, Rutland. The following members of the faculty of the University of Rochester School of Medicine and Dentistry, Rochester, N. Y., will be the guest speakers:

- Dr. Charles M. Carpenter, Diagnosis and Control of Gonococcal Infections.
- Dr. Samuel W. Clausen, The Importance of Congenital Obstructions of the Intestines as a Cause of Vomiting in Infancy.
- Dr. William S. McCann, Practical Considerations of the Newer Physiologic Studies of Renal Disease.
- Dr. Stafford L. Warren, Survey of the Newer Aspects of Radiographic Diagnosis in Relation to the General Practitioner.
- Dr. Winfield W. Scott, Hematuria.
- Dr. Karl M. Wilson, The Use of X-Rays as a Diagnostic Aid in Obstetrics and Gynecology.
- Dr. William L. Bradford, Active and Passive Immunity Against the Common Infectious Diseases.
- Dr. William J. Merle Scott, Some Problems in Gastric Surgery.

Dr. Ball will deliver his presidential address on "Medical Vision"; Dr. Wilmer W. Angell, Randolph, the vice presidential address on "The Challenge of the Small Hospital," and

Dr. Hardy A. Kemp, dean and professor of bacteriology and preventive medicine, University of Vermont School of Medicine, Burlington, will speak on "Plans for Postgraduate Medical Education in Vermont."

A special program of ophthalmology and otolaryngology has been arranged with the following speakers:

- Dr. David Harold Walker, Boston, Practical Consideration of Ear Diseases.
- Dr. Deforest C. Jarvis, Barre, Twelve Varieties of the Common Cold.
- Dr. Walter B. Lancaster, Boston, Difficulties Encountered in Measuring Errors of Refraction.

There will also be a special meeting on pathology and radiology at which cases of cancer of the stomach will be presented, and Dr. Robert J. Stein, Newport, will read a paper on "Stromal and Systemic Changes in Carcinoma of the Breast."

The Vermont regional committee on fractures of the American College of Surgeons will present a symposium with the following speakers: Drs. Henry C. Marble, Boston, "Compound Fractures"; Andrew William Reggio, Boston, "Important Points in the Treatment of Ankle-Joint Fractures," and Otto J. Hermann, Boston, "Injuries to the Wrist and Foot."

WYOMING

Plague Infection.—According to *Public Health Reports*, plague infection has been proved in a pool of fifty-four fleas from twenty-two ground squirrels, in tissue from one ground squirrel, all from a locality from 8 to 10 miles north of Kendal Ranger Station, Sublette County, Wyo., and in a pool of eighteen fleas from fourteen ground squirrels taken from 12 to 15 miles north of the same station. The ground squirrels, all of the same species, *C. armatus*, were all shot the same day, August 6.

GENERAL

Regional Meeting of Obstetricians and Gynecologists.—The twelfth annual meeting of the Central Association of Obstetricians and Gynecologists will be held in Indianapolis, October 10-12, at the Hotel Lincoln, under the presidency of Dr. Jennings C. Litzberg, Minneapolis. Dr. Robert Otto Meyer, Minneapolis, will be the guest speaker on "Some Aspects of the Pathology of Hydatidiform Mole and Chorion-epithelioma." Among other speakers will be:

- Drs. Carl P. Huber and Jack C. Shrader, Indianapolis, Blood Prothrombin Levels in the Newborn (the clinical prize award essay).
- Dr. Harold Henderson, Detroit, The Relative Effect of General and Local Anesthesia on Asphyxia Neonatorum.
- Dr. John R. Wolff, Chicago, The Leukocyte Count in Labor.
- Drs. Harry L. Stewart Jr. and Jean P. Pratt, Detroit, Inhibition of Lactation.
- Dr. Phillips J. Carter, New Orleans, Conglutination Orificii Externi as a Factor in Delayed Labor.

Infantile Paralysis Fund Raised on President's Birthday.—The Committee for the Celebration of the President's Birthday reported to President Roosevelt, September 24, that the 1940 "Fight Infantile Paralysis Campaign" raised a net total of \$1,407,245.74. Of the total net proceeds, \$768,780.29 remained in the communities and chapters of the National Foundation for Infantile Paralysis throughout the country. The foundation received \$638,465.45 to carry on its work aimed toward eradicating and controlling the disease. The major part of the fund was raised by the parties and dances held on the President's birthday, January 30, and by sports events promoted by the "March of Sports." The "March of Dimes" raised a net total of \$250,205.07. California led the states in the net total raised, \$209,042.26; New York was second with \$199,258.38, and Pennsylvania third with \$86,644.67. The foundation's work is carried on through grants issued to universities, colleges and hospitals for research; it aids hospitals and institutions in the treatment of after-effects of the disease, distributing information on diagnosis and treatment and on the use of iron lungs, splints and braces. It sends doctors, nurses, epidemiologists, respirators and splints into towns and cities where they are needed. The chapters are working with health authorities and physicians in epidemic regions, using chapter funds to see that no case is neglected, according to the committee's report. The total number of cases this year exceeds the total for the same period last year, the principal outbreaks being in Washington, West Virginia, Indiana, Ohio, Michigan, Iowa, Kansas, Illinois, Kentucky and Montana. The number up to September 7, according to figures compiled by the U. S. Public Health Service, was 4,037, compared with 3,454 for the same period in 1939. Mr. Basil O'Connor, New York, is president of the National Foundation for Infantile Paralysis and Mr. Keith Morgan, New York, is national chairman of the Committee for the Celebration of the President's Birthday.

Examination of the Recruit's Heart

A committee appointed by the government, under the chairmanship of Lord Horder, to advise on the examination of recruits has presented recommendations on the methods of detecting "the effort syndrome" and diseases of the heart and arteries. The committee has submitted recommendations which amend and amplify the instructions existing for the guidance of medical boards. The committee was assisted in its work by the Cardiac Society of Great Britain and Ireland and by Sir Thomas Lewis and Dr. Paul Wood. "Effort syndrome" is defined as a condition in which the characteristic symptoms are nervousness, a feeling of exhaustion, left mammary discomfort, palpitation, giddiness and dyspnea on exertion. Many men break down during training or on active service with these symptoms. The great majority of them are neuropathic but in a small group the symptoms are attributable to chronic or temporary toxemia. The condition is rarely an expression of any disorder of the heart. A board may be able to foretell that certain recruits, by their appearance and demeanor and by evidence of nervous instability, are likely to break down in this way. Habitual avoidance of exertion in recreation is particularly suggestive. An exercise tolerance test affords little guidance in detecting potential sufferers from this syndrome but may be valuable in gaging the degree of emotional disturbance when the characteristic symptoms are already manifest.

The following revised form of tolerance test is now prescribed. 1. The pulse rate is taken for fifteen seconds with the man standing. 2. The man places one foot on a chair at least 15 inches high. He then raises himself until both feet are on the chair and the body is upright. He then lowers himself until one foot is on the floor. This is repeated twenty times in sixty seconds. The pulse is then taken for fifteen seconds. 3. The man stands still, and forty-five seconds later the pulse is taken for fifteen seconds. It should then be the same as or lower than the original rate. The persistence of any dyspnea or distress should be noted. If the original pulse rate is regained in sixty seconds and there is no dyspnea or distress he may be regarded as having good exercise tolerance. If the response is unsatisfactory the cause may be nervous instability or some cardiovascular defect and must be investigated. The test alone does not afford conclusive evidence of these conditions or of the man's unfitness for grade 1. The test may be rendered misleading by temporary factors such as a common cold or lack of fitness following prolonged sedentary work.

The heart should always be examined while the man is standing and also while he is lying on his left side; otherwise heart murmurs are difficult to detect. They should be listened for on both sides of the sternum and while the breath is held in full expiration. A man should be classed as in grade 4 whose heart shows signs of enlargement, aortic or mitral disease or congenital heart disease, even though well compensated and the existence of a fair response to the exercise tolerance test. A systolic murmur heard at the apex is not to be accepted alone as evidence of organic disease, but high grade exercise tolerance should be required and mitral or aortic disease carefully excluded. If the systolic bruit is slight and the only sign, the man may be accepted as of grade 1 provided he has good exercise tolerance. A systolic murmur at the base is common in health and may be disregarded when loudest in the pulmonary area, unless associated with other signs of congenital heart disease. If loudest in the aortic area, transmitted upward and accompanied by a thrill, it indicates aortic stenosis.

If the cardiac impulse is felt beyond the midclavicular line, the heart is enlarged provided the displacement is not due to scoliosis or to pulmonary disease. The commonest causes of enlargement are aortic and mitral disease; less common causes are hypertension and congenital heart disease. Abnormal rhythm is not necessarily evidence of organic disease. Before grading, the previous history (occupation, athletic habit and other activities) must be reviewed as well as the exercise tolerance test. Tachycardia is most often an expression of nervousness, but if paroxysmal requires a low grading. Hyperthyroidism should be excluded. Cases of arrhythmia and tachycardia of doubtful nature should be referred to a consultant. In all men over 40 and in any case of cardiac enlargement or of suspected arteriosclerosis the blood pressure should be taken.

The Medical Women's Federation and the Prevention of Venereal Disease

The Medical Women's Federation has taken a strong interest in the problem of venereal disease. It has issued a statement pointing out that the large numbers of men and women in the fighting forces render the prevention of venereal disease important. The most effective way would be welfare services available to all. These would provide not only ample arrangements for healthy recreation but also education and advice in matters of health. The work of welfare officers has already proved valuable in maintaining good morale, but the staff should be augmented by suitably qualified men and women, and individual private hospitality should be welcomed in association with the official organization. Provision of this kind is of primary importance in the prevention of venereal disease.

The federation emphasizes the importance of sex teaching with the object of developing a social conscience in men and women. Education in sex hygiene should be given to all members of the fighting forces, both men and women. For women this should be given by medical women who have special experience in social hygiene. Members of the women's forces who contract venereal disease should not necessarily be dismissed but given adequate and sympathetic treatment. They should have facilities similar to those of men and have access to medical women. The federation emphasizes its belief that *maisons tolérées* are a danger to health and likely to increase venereal disease. Further, although some individual infection may be prevented by the use of "prophylactic packets," their routine distribution, by implying official sanction of illicit intercourse, tends to increase promiscuity and the incidence of venereal disease. Welfare facilities, education and treatment should also be fully available for munition workers, especially those working for long hours.

Medical Aid at the Battle Front

• Prof. Filippo Ferraro, who was chief of sanitation of a division of volunteers in the Spanish civil war, recently discussed in Genoa modern medical units in mobile warfare. The new ideas in military tactics and in the use of weapons necessarily have changed also the operation of the divisional medical service. Medical units in war can no longer be considered relatively stationary; on the contrary, they must meet the needs of rapid shifts of position, intensified by aerial warfare, and must follow troops in action to within the nearest distance possible. They must maintain medical equipment at all times at the highest efficiency. Basing his observations on the statistics gathered during the battles of Guadalajara and Santander, regarded by military experts as two of the most typical modern battles, the speaker pointed out that the proportion of divisional losses sustained was, on the average, 8 per cent as

compared with a 20 per cent loss recorded for the war of 1914-1918. The index for seriously wounded was about 9.5 per cent. In comparison with Italian statistics for the World War indicating 39.1 per cent as wounded by small arms and 19.5 per cent by artillery, present statistics indicate 69.3 per cent as wounded by small arms and 19.5 per cent by artillery. Seven and eight tenths per cent were wounded by bombs discharged from airplanes and 7.8 per cent by explosion of mines. As to the site of traumatic lesions, important from the point of view both of medical technic and of the handling of the wounded in the field, there was a relative increase in wounds of the lower extremities, compared with the statistics for the war of 1914-1918. The percentage for wounds of the abdomen and thorax remained practically unchanged. Mortality on the battlefield amounted to 15.7 per cent. This is in accord with the general average accepted by military medical statistics. Deaths due to freezing and gassing were few. Military physicians, he said, were not all in accord in regard to specialized surgical service. Experience had taught him that the principal function of what is referred to as the "surgical nucleus" was early intervention for all wounded promising recovery. In fact, Ferraro's statistics indicated that the shorter the distance of the "surgical nucleus" from the battle line the lower the mortality rate among the wounded and even among those operated on. Since establishing a position and getting ready required time, he favored the idea that the "nucleus" be attached either to a less advanced unit of the medical service or to an advanced field hospital. However, a more practical suggestion would be to divide the "nucleus" into two parts so as to guarantee continuity of service on the relay plan. The divisional medical staff might also request to have placed at its disposal reserve groups of surgeons to meet the need of excessive demands occurring on the same day.

Changes in the Volume of Circulating Blood

Professor Bertola discussed before the society of physicians and surgeons of Pavia the modifications which the volume of circulating blood may undergo in response to certain factors. Modifications may be caused by changes in the position of the subject during the action of certain drugs on the vegetative nervous system. In the change from a recumbent to a standing position, increases as well as decreases of the circulating blood were observed. The increases were accompanied on the whole by a lowering of the arterial blood pressure, whereas an increase in pressor levels accompanied the diminution of the circulating blood.

During the action of atropine, in general, hypovolemia prevailed in subjects in the standing position combined with hypotensive reactions and a diminution of pulse frequency. The opposite behavior was noted during the action of pilocarpine. Ergotamine showed a behavior analogous to that induced by atropine, whereas epinephrine generally increased the circulation of the blood when subjects stood and showed an increase in the pressor levels and pulse frequency. In short, substances which stimulated the vagus and the sympathetic nerve produced predominantly hypervolemia in the standing position, whereas those with inhibitory action showed a contrary behavior.

Investigations into the modifications of the volume of circulating blood and of other factors during digestion both in normal subjects and in patients with gastric disorders showed regularly an increase in the volume of circulating blood after the administration of carbohydrates, proteins, fats, salts or a mixed diet. In patients with ulcers, on the contrary, a decrease in the volume of the circulating blood was regularly observed. These results may be explained by the fact, he said, that certain organs may be regarded as filled with blood owing to the regulator function of the vegetative nervous system.

Studies of the regulatory effect of the carotid sinus on the behavior of the circulating blood when the subject changed

from a recumbent position to one with the head down prevailingly indicated in normal and hypotensive persons a decrease in the circulating blood, which at times was considerable, together with an increase in the rate of circulation. In hypertensive persons, on the other hand, there were pronounced variations in the volume of the circulating blood, generally in the direction of increases. Present knowledge cannot satisfactorily explain the factors that produce these differences. However, Ferraro stressed certain facts such as the opposite behavior of pulse reaction, of arterial pressure and of the volume of circulating blood, which is typical for hypertensive persons and rare in normal and hypotensive subjects. The importance of the action of organs which act as depositories of blood and which are prevailingly regulated by the vagus and the sympathetic nerve is not overlooked. Yet the possibility is not excluded that reflex vasomotor modifications under the influence of the vasoreceptor zones may interfere with the regulation of the circulating blood.

Deaths

Prof. Luigi Sestini, physician general of the navy and a war invalid, died at Spezia. He was highly esteemed. Among the positions of responsibility held by him was the directorship of the School of Health in Naples. His special interest lay in promoting health in the navy by the institution of sanitary improvements on war vessels and by combating tuberculosis.

Marriages

WILLIAM KENNETH MASSEY, Ashcroft, B. C., Canada, to Miss Corinne Kearfoot Saunders of Winnipeg, Man., recently.

BRIAN DESMOND BEST, Winnipeg, Man., Canada, to Miss Jean Margaret Prior of Portage La Prairie, June 29.

JAMES ROY BREED, Wappingers Falls, N. Y., to Miss Jocelyn Harrington of Poughkeepsie, September 7.

JAMES PORTER LEATHERS, Nashville, Tenn., to Miss Katheryne Bowden McClain of Lebanon in August.

WILL HARDEE LASSITER JR., Selma, N. C., to Miss Kathleen Anderson of Winston Salem in August.

EMANUEL BARNETT HECHT, Ancon, Canal Zone, to Miss Adele Weinstock of New York, July 25.

ROBERT T. McMAHON, Albany, Calif., to Miss June Huml of Oakland, July 13, in Carson City, Nev.

EILIF CARL HANSSEN, New York, to Miss Carroll Ellicott Henderson at Los Angeles, June 21.

CLAUDE FREDERICK OTTEN, Morristown, N. J., to Miss Lois Heuse of Dallas, Texas, August 17.

ROBERT WOOLFORD, Hamilton, Ohio, to Miss Mary Margaret Kilgore in Columbus, September 1.

WILLIAM B. LYBROOK, Young America, Ind., to Miss Betty Lou Etnire of Logansport, June 25.

EDMOND CHADWICK CAMPBELL, Morganza, La., to Miss Edna Peresich at Monroe, August 4.

LOYD E. ROSENBAUM, Anderson, Ind., to Miss Doris Nussbaum of St. Louis, August 5.

MARVIN R. DAVIS, Letts, Ind., to Miss Martha Louise Banister of Columbus, July 6.

RICHARD L. VARCO, Minneapolis, to Miss Louise Miller at Pasadena, Calif., June 4.

WILLIAM B. ARMSTRONG to Miss Henrietta Collier, both of Atlanta, Ga., August 1.

STANLEY LLOYD TEITELMAN to Miss Bobette Wilson, both of Chicago, August 31.

JOSEPH RAIDER, Mundelein, Ill., to Miss Beatrice Goldsmith of Chicago, August 22.

DAVID F. STONE to Miss Katherine Charlotte Weiss, both of Indianapolis, June 28.

EMIL A. HOFER, Iroquois, S. D., to Miss Ann Hodges of De Smet, June 27.

LAWRENCE M. DUNN to Miss Gertrude Grbac, both of Depue, Ill., August 10.

Deaths

Grant Phileo Curtis ☉ Union City, N. J.; Jefferson Medical College of Philadelphia, 1906; health officer; served during the World War; for many years attending physician at the Hudson County Penitentiary; consulting phthisiologist at Margaret Hague Hospital, Jersey City; consultant at Hudson County Tuberculosis Hospital, Jersey City; aged 55; died, August 28, in the Hospital for Ruptured and Crippled, New York, of acute pancreatitis.

Lewis Leonidas Rogers Jr., ☉ Wilkes-Barre, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1913; member of the Radiological Society of North America; past president of the Luzerne County Medical Society; served during the World War; was a member of the school board of Kingston; aged 50; on the staffs of the Mercy Hospital and the Wilkes-Barre General Hospital, where he died, August 11, of arterio-vascular nephrosclerosis.

Guy Sexton Carpenter ☉ Waverly, N. Y.; Cornell University Medical College, New York, 1899; past president of the Tioga County Medical Society; health officer of the village of Waverly and the town of Barton; aged 66; on the staff of the Tioga County General Hospital, where he died, August 28, of cerebral hemorrhage.

George Edward Harhen, Caldwell, N. J.; Long Island College Hospital, Brooklyn, 1912; member of the Medical Society of New Jersey; at one time physician in charge of the Newark City Sanatorium, Verona; aged 53; on the staff of St. Vincent's Hospital, Montclair, where he died, August 24, of cerebral hemorrhage.

Joseph Whitman Sherer ☉ Kansas City, Mo.; State University of Iowa College of Medicine, Iowa City, 1894; University of Pennsylvania Department of Medicine, Philadelphia, 1895; fellow of the American College of Surgeons; aged 70; died, August 17, at Excelsior Springs, of injuries received in an automobile accident.

Charles Dana Hunter, Tacoma, Wash.; Rush Medical College, Chicago, 1905; member of the Washington State Medical Association and the North Pacific Surgical Association; fellow of the American College of Surgeons; served during the World War; aged 60; died, August 5, of coronary thrombosis.

Joseph Archibald Robertson ☉ Dallas, Texas; University of Texas School of Medicine, Galveston, 1898; fellow of the American College of Surgeons; attending surgeon, St. Paul's, Dallas Methodist and Baylor hospitals; consulting surgeon to the Parkland Hospital; aged 65; died, August 18, of coronary occlusion.

Oscar Ewing Townsend, Elyria, Ohio; Eclectic Medical College, Cincinnati, 1911; Medical Department of the University of Cincinnati, 1912; member of the Ohio State Medical Association; served during the World War; on the staff of the Elyria Memorial Hospital; aged 54; died, August 17, of heart disease.

James Monroe Peterson, Spruce Pine, N. C.; Tennessee Medical College, Knoxville, 1902; veteran of the Spanish-American and World wars; at one time postmaster; formerly county superintendent of public instruction; aged 68; died, August 19, in Johnson City, Tenn., of carcinoma of the lung.

Cornelius Wilson Lane ☉ Castle Rock, Wash.; Hahnemann Medical College and Hospital, Chicago, 1905; at one time health officer of Del Norte County, Calif.; for many years a member of the United States Indian Service; aged 56; died, August 13, at Longview, Wash., of coronary thrombosis.

Thomas Scholz ☉ New York; Columbia University College of Physicians and Surgeons, New York, 1916; aged 58; on the staffs of St. Joseph's Hospital, New York Foundling Hospital and St. Francis Hospital, where he died, August 28, of diabetes mellitus and chronic nephritis.

William Baird Andrews ☉ Kent, Ohio; Homeopathic Hospital College, Cleveland, 1890; for many years member of the county board of health, president of the board of health of Kent and member of the board of education; aged 73; died, August 28, of angina pectoris.

James Tertius Norton, Kent, Ohio; Western Reserve University Medical Department, Cleveland, 1910; served during the World War; formerly on the staff of the Babies Hospital, Cleveland; aged 56; died, August 27, of coronary thrombosis and cerebral embolus.

John David Gable, Lake City, Fla.; University of Nashville (Tenn.) Medical Department, 1908; served during the World War; aged 67; on the staff of the Veterans Administration Facility, where he died, August 13, of arteriosclerosis and coronary heart disease.

Edward Lowell Saylor ☉ Akron, Ohio; University of Kansas School of Medicine, Kansas City, 1925; member of the American Society of Clinical Pathologists; aged 39; on the staff of the City Hospital, where he died, August 10, of a self-inflicted bullet wound.

Edward King Tyler, Muscatine, Iowa; State University of Iowa College of Medicine, Iowa City, 1882; member of the Iowa State Medical Society; aged 81; on the staff of the Benjamin Hershey Memorial Hospital, where he died, August 3, of chronic bronchitis.

Willard McKenzie Burleson, Richmond, Va.; Medical College of Virginia, Richmond, 1937; member of the Michigan State Medical Society; resident, Medical College of Virginia, Hospital Division; aged 28; was killed, August 31, in an airplane accident.

Nils Olof Byland ☉ Battle Creek, Mich.; University of Michigan Medical School, Ann Arbor, 1922; served during the World War; for many years on the staff of the Battle Creek Sanitarium; aged 59; died, August 29, of heart disease.

John William Leo Brennan, St. Louis; St. Louis College of Physicians and Surgeons, 1906; aged 58; died, August 28, in the Veterans Administration Facility, Jefferson Barracks, of hypertensive and coronary arteriosclerotic heart disease.

Ernest Gollub, Staten Island, N. Y.; Jefferson Medical College of Philadelphia, 1937; on the staff of the Sea View Hospital; aged 28; died, August 27, in the Post-Graduate Hospital, New York, of mastoiditis and brain abscess.

Theodore Perry Bishop, Grand Rapids, Mich.; University of Michigan Medical School, Ann Arbor, 1921; member of the Michigan State Medical Society; aged 51; died, August 29, in the Butterworth Hospital of tumor of the right adrenal.

Samuel Albert Jones, Sheffield, Vt.; University of Vermont College of Medicine, Burlington, 1883; member of the Vermont State Medical Society; aged 83; died, August 11, of cerebral hemorrhage and arteriosclerosis.

Rolla Camden, Parkersburg, W. Va.; Jefferson Medical College of Philadelphia, 1897; on the staff of the Camden-Clark Memorial Hospital and St. Joseph's Hospital; aged 67; died, August 22, of chronic nephritis.

Henry Gray Morris ☉ Jamestown, N. Y.; Cornell University Medical College, New York, 1921; member of the Radiological Society of North America, Inc.; aged 44; died, August 20, of cerebral hemorrhage.

John Ralph Coryell, Kansas City, Mo.; University of Virginia Department of Medicine, Charlottesville, 1909; aged 54; died, July 9, in St. Luke's Hospital of ruptured esophageal varices and cirrhosis of the liver.

Robert James McDonald, Doylestown, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1901; aged 69; died, August 17, in Columbus of pernicious anemia.

Frank James Pherson, Manchester, N. H.; Jefferson Medical College of Philadelphia, 1908; member of the New Hampshire Medical Society; aged 59; died, August 27, in Boston of heart disease.

Paul Martin Lennox, Colorado Springs, Colo.; Columbia University College of Physicians and Surgeons, New York, 1903; aged 59; died, August 28, in the Beth-El General Hospital of pneumonia.

Austin Emery St. Clair, Framingham, Mass.; University of Vermont College of Medicine, Burlington, 1893; member of the Massachusetts Medical Society; aged 75; died, August 7, of arteriosclerosis.

John Wesley Barkley, Ligonier, Pa.; Jefferson Medical College, Philadelphia, 1897; member of the Medical Society of the State of Pennsylvania; aged 72; died, August 29, of cardiovascular disease.

Thomas Blair, Ann Arbor, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1892; aged 79; died, August 28, in the University Hospital of perforated duodenal ulcer.

J. Thomas O'Toole, Oklahoma City; Independent Medical College, Chicago, 1898; aged 79; died, July 7, in St. Anthony Hospital of arteriosclerosis and heart disease.

Correspondence

CARBOHYDRATES AND HEADACHE

To the Editor:—With reference to the relationship between the ingestion of carbohydrates and the development of headaches, you make the statement (Queries and Minor Notes, THE JOURNAL, July 6, p. 75) that Wagner-Jauregg and Porges purported to show that a low carbohydrate diet is beneficial in cases of migraine. This suggestion was first made by me (A New Approach to Dietetic Therapy, Boston, R. G. Badger, 1933; A New Aspect of Migraine and Certain Related Conditions, *Am. J. Digest. Dis. & Nutrition* 1:359 [Aug.] 1934, and so on), as admitted by Wagner-Jauregg in a personal communication. I offered the theory that low carbohydrate diet is effective in the prevention of migraine by preventing the development of cerebral edema. A recent publication (Migränebehandlung mit kohlehydratarmer Diät, *Klin. Wchschr.* 18:390 [March 18] 1939) summarizes my observations and theories and contains the pertinent bibliography.

EUGENE FOLDES, M.D., New York.

BUNDLES FOR BRITAIN

To the Editor:—The situation in England is one of intense suffering. Surgical instruments and equipment are urgently needed NOW. Will you please help me to help the doctors and surgeons at home to relieve this suffering by publishing this letter together with the enclosed list of instruments? This list has just been flown across to me by clipper, from a source of highest authority in London.

Instruments Urgently Needed in British First Aid Stations

Airways, endotracheal	Gorget, lithotomy	Speculums, ear, eye, nasal, rectal
Apparatus, anesthetic (portable)	Gouges, bone	Sphygmomanometer, aneroïd
Apparatus, intravenous	Headbands, metal, with mirrors	Stands for irrigators
Aspirators	Hemostats, all types	Sterilizers, all
Autoclave	Holders, needle	Stethoscopes
Basins	Inhalers, chloroform	Stools, anesthetists', with revolving top
Cabinets, instrument	Knives, all types	Stools, foot
Cannula, brain exploring	Lamps, operating, emergency, complete	Syringes, all sizes, with needles
Catheters	Mallets, metal, lead filled	Tables, instrument
Chisels, bone	Mirrors, laryngeal	Tables, operating
Clamps, bone plating	Pharyngoscope with battery in handle	Trocars
Clamps, intestinal	Plates, bone	Tubes, tracheotomy
Clips, towel	Pliers, side cutting, 6 inch	Wax, bone, sterile
Curets, mastoid	Probes, all types	Buckets
Diagnostic sets	Retractors, all types	Clippers, hair
Depressors, tongue	Rings, laparotomy	Cups, medicine
Directors, grooved, with myrtle leaf	Saws, all types	Jugs, graduated
Drill, bone	Scissors, all types	Measures, glass, graduated
Drills, cranial	Screws, bone plating	Pans, bed, enamel
Elevators	Shears	Pitchers, 3 quart
Forceps, artery, all types	Snare	Stoves, petrol or paraffin, table model
Forceps, bone, rongeurs	Sounds, metal	Tables, bedside
Gags, mouth, Denhart	Spatula	Urinals, E. I.

I feel this is the quickest way to appeal to all doctors in the hope that they will read this and send their surplus instruments to me at the address below. All contributions will be sent to England at once, where they will help to save many lives that may otherwise be lost.

RAFAELLE LEINSTER,
The Duchess of Leinster,
Surgical Supplies,
745 Fifth Avenue,
New York.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

FORMALDEHYDE STERILIZATION OF FOOTWEAR

To the Editor:—Please give detailed directions for fumigating shoes with formaldehyde.
M.D., Illinois.

ANSWER.—Shoes, slippers and other footwear should be sponged each week with 10 per cent solution of formaldehyde or they can be placed in a closed box together with a dish of solution of formaldehyde for twenty-four hours. After each sponging or exposure to the formaldehyde fumes, articles should not be worn before airing for at least twenty-four hours. Failure to carry out the last precaution may result in a dermatitis from the formaldehyde vapor. Henderson and also Ayres, Anderson and Youngblood have found formaldehyde vapor an effective means of fumigation.

Cotton socks worn by patients with tinea pedis should be boiled for ten minutes or immersed for half an hour in a 1:1,000 solution of mercury bichloride. They may then be washed with soap and water or sent to the laundry. Woolen and silk stockings may be ruined by boiling, but the use of formaldehyde vapor in a box will be found effective.

SHIPPING BLOOD FOR AGGLUTINATION TESTS

To the Editor:—What is the opinion of hematologists on the cross-matching value of both red blood cells in a 2 per cent sodium citrate solution of physiologic solution of sodium chloride and blood serum which has remained at temperatures such as might be encountered in the ordinary methods of transportation? If such cells and serum had remained for twenty-four hours at a temperature ranging from 90 to 100 F. would these both still be suitable in cross-matching prior to transfusions?

M.D., Oklahoma.

ANSWER.—Red blood cells in suspension in sodium citrate solution or physiologic solution of sodium chloride together with the blood serum, when shipped through the mails, are not suitable for grouping or cross-matching tests for transfusion. The best method to ship blood is to collect the blood as for a Wassermann test and send the clotted blood sample by air mail, special delivery, if the destination is any considerable distance away. The package should be marked "Avoid excessive heat and cold." The blood should be taken with sterile precautions, placed in sterile tubes and hermetically sealed with a sterile rubber stopper or in the flame. Under these conditions twenty-four hours at from 90 to 100 F. probably will not spoil the sample, there being no bacterial contamination. Blood cells in dilute suspension quickly lose their sensitivity for agglutination, even if sterile, whereas in the clotted form this is retained for much longer periods. In addition, dilute blood suspensions, especially when infected with certain bacteria, may become "panagglutinable" and are also more apt to agglutinate spontaneously or hemolyse.

As far as the serum is concerned, agglutinins will deteriorate gradually at 90 to 100 F., though the common iso-agglutinins α and β should be demonstrable for at least a week and usually much longer under such conditions, provided the sample is not infected. Not infrequently, however, the iso-agglutinins are of low titer and such will deteriorate rapidly. Moreover, irregular agglutinins, which are almost invariably of low potency, despite the fact that they can give rise to severe hemolytic reactions even though the groups of patient and donor are identical (Wiener, A. S., and Peters, H. R.: Hemolytic Reactions Following Transfusions of Blood of the Homologous Group, with Three Cases in Which the Same Agglutininogen was Responsible, *Ann. Int. Med.* 13:2306 [June] 1940) will probably not be demonstrable under these conditions.

Accordingly the best method, as stated, is to ship the blood in clotted form. The individual receiving the sample can

separate the serum by centrifuging. Blood suspensions can be prepared by shaking up the clot in saline solution; the coarser particles are allowed to sediment and the supernatant smooth emulsion is transferred to a clean tube for use in the grouping tests.

FUNGUS INFECTION OF NAILS

To the Editor:—I have recently seen two cases of fungous infection of the finger nails. I have not yet received reports of the cultures which have been made. Any information you may have regarding this condition, particularly as regards effective treatment, will be appreciated.

M.D., Kentucky.

ANSWER.—Infection of the nails by fungi was formerly considered a rarity, but the experience of all dermatologists contradicts this. Whether the infecting organism is one of the yeastlike fungi or belongs to the hyphomycetes the symptoms are apt to be much the same, though the yeastlike organisms are more liable to cause acute inflammation, involvement of the nail folds and pus formation. Oláh (Neuere Beiträge zur Klinik u. Therapie der Mykogenen Onychien u. Paronychien, *Dermat. Wchnschr.* 103:1189 [Aug. 29] 1936) has emphasized the fact that stippling of the nail, Beau's punctae, as seen in psoriasis, is sometimes one of the signs of such infection. In both infections, thickening of the nail, discoloration, fissuring, scaling, brittleness, partial or complete separation from the nail bed, thinning or even almost complete destruction may be seen. Sulzberger and Lewis (Leukonychia Tricophytina, *M. Rec.* 146:305 [Oct. 6] 1937) have reported white spots which consist of masses of spores and mycelium in the lower part of the nail next the nail bed, caused by *Tricophyton gypsum*.

The treatment of these cases is one of the difficult problems of dermatology. In cases in which the yeastlike infection is brought on by constant immersion of the hands in dish water or in fruit juices, as described by Kingery and Thienes (Mycotic Paronychia and Dermatitis, *Arch. Dermat. & Syph.* 11:186 [Feb.] 1925) abstention from the work and mild applications, such as a 10 per cent solution of sodium thiosulfate in water may suffice; but most cases require more energetic measures. Puncture of the nail, if pus is seen beneath it, and wet dressings of the thiosulfate solution, painting with 5 per cent watery solution of gentian violet, or the use of mercurials such as ammoniated mercury ointment may succeed in producing cure. Iodides by mouth or sodium iodide intravenously, with tincture of iodine applied locally, is successful in some cases. In all chronic forms of either yeastlike or hyphomycetic infection the nail must first be thinned, either by direct scraping or by filing, or by first softening it by soaking it in soap solution for twenty-four hours or the application of a strong potassium hydroxide solution for a short time (45 per cent solution for fifteen minutes). The nail folds should be protected by petrolatum. This thinning process must be repeated once or twice a week. After this thinning has been carried as far as practical, three methods are open to the physician: chemical attack, actinic action or surgical ablation of the nail.

Chemical methods are many besides those already mentioned. Stelwagon applied a 0.2 to 1 per cent solution of mercury bichloride in water followed by ammoniated mercury ointment. Harrison used a 50 per cent solution of potassium hydroxide in water, to eight parts of which he added one part of potassium iodide, for softening. This he allowed to act for fifteen minutes. He then applied a 1 per cent aqueous solution of mercury bichloride for twenty-four hours. Glaze used a saturated aqueous solution of sodium thiosulfate; others apply diluted acetic acid and then mop on a 6 to 10 per cent solution of the thiosulfate. Dubreuilh advocated the application of equal parts of pyrogallol and olive oil. Sutton advocates the use of 10 per cent silver nitrate solution in alcohol. It must be a somewhat diluted alcohol to dissolve this amount of silver nitrate. Cleveland White uses a strong Whitfield ointment, 12 per cent of salicylic acid and 24 per cent of benzoic acid. Way uses 1 per cent malachite green, 2 per cent phenol, 5 per cent salicylic acid and 24 per cent alcohol in xylene, painted on twice daily. Walker dresses the nail with Fehling's solution for two days, then removes the nail and applies a dressing of 2 per cent copper sulfate in water.

Combining chemical with actinic action is the method of Paulina Gomez-Vega, who determined by a careful research that a solution of mercurochrome 1 part to 10,000 sensitizes the organisms to the action of sunlight. Her results in a small

number of cases were encouraging. (Effect of Irradiation and Irradiation plus Sensitization on Yeastlike Fungi and Related Organisms, *Arch. Dermat. & Syph.* 34:961 [Dec.] 1936).

MacKee (X-Rays and Radium in the Treatment of Diseases of the Skin, ed. 3, Philadelphia, Lea & Febiger, 1938, p. 480) uses hot soap suds for softening the nail; soaking it for an hour or two, then scraping it as thin as possible. For two weeks preceding the treatment, during the period of irradiation or for two weeks after the series of treatments has ended, he does not allow the use of any strong chemicals. While he thinks that a 1:5,000 solution of mercury bichloride, a 3 per cent ammoniated mercury ointment or 3 per cent precipitated sulfur ointment would be permissible, he does not allow his patients to use anything stronger than soap and water.

Because of the absorption of rays by the nail plate in spite of the reduction in its thickness, some filtration of the x-rays is called for and a larger dose of rays is advisable over the nail than could be used safely on the skin. In case of combined onychia and paronychia both nail and nail fold may be first irradiated with fractional doses, then the nail fold covered by lead and an additional dose given the nail itself. He permits several nails to be treated at one exposure, both thumb nails or big toe nails, for instance. The prognosis seems better for irradiation than for chemical treatment. Relapses are not common.

Most dermatologists do not favor surgical ablation of the nail because of the frequency with which the new nail is infected.

EXTERNAL HEMORRHOIDS AND PECTINOSIS

To the Editor:—What is the treatment of varicosities of the anal margin? Can four or five varicose veins, first degree in nature, bring on symptoms severe enough to make the patient constantly uncomfortable? She complains of burning in the rectum with pains radiating to the lumbar regions and thighs. The patient, 62 years old, has a history of a number of injections for hemorrhoids. The original symptoms of prolusion and bleeding cleared up, but the pain and burning described developed and persisted for about nine months without relief. A proctologist was consulted and a diagnosis of chronic proctitis was made, due to injections made in the presence of infection. Fissure, fistula and the like were ruled out. The urine was normal. The proctoscopic examination disclosed induration throughout the wall of the rectum. This does not respond to treatment. Is it to be considered that injection of hemorrhoids may have resulted in the dilatation of the veins around the anus? Would it be safe to inject these veins with sodium morrhuate?

M.D., New York.

ANSWER.—External hemorrhoids are usually unsuitable for injection treatment. In the case described it would be important to determine whether or not the varicosities are distal to the pectinate line, as injections should never be made distal to it. A pathologic thickening of fibrous tissue as a result of congestion and infection was described by W. Ernest Miles in 1918 as the pecten band and the condition was named pectenosis. It is conceivable that the injections were made into so-called mixed varicosities, obliterating the internal hemorrhoids and leaving the dilatations intact below the anal membrane or the perianal skin. The anal canal and the region of the pectinate line are extremely sensitive owing to the rich supply of sensory nerve endings. In the case mentioned chronic cryptitis or papillitis should be considered. The management of these calls for an expert proctologist.

LIPOCAIC AND LIPOLYSIN

To the Editor:—In reference to the article by Dr. Dragstedt in The Journal, January 6, can you tell me if the substance Dragstedt describes is the same as Dr. J. B. Wolfe's lipolysin? M.D., New Jersey.

ANSWER.—Lipocaic is the name suggested by Dragstedt and his associates for a substance present in extracts of pancreas which they believe represents a specific hormone concerned in the utilization and transport of body fat. The beneficial effects of the oral administration of fresh pancreas in prolonging the lives of depancreatized dogs treated with insulin and in preventing the usual fatty infiltration of the liver which occurs in these animals is due to the presence of this hormone and not to the amount of choline or lecithin present in the pancreas.

They have suggested the following criteria as indicating the presence of lipocaic in various pancreas extracts: A minimum of three normal dogs should be completely depancreatized and placed on a diet of protein, carbohydrate and liberal amounts of fat and given sufficient insulin to limit the glycosuria to less than 10 Gm. a day. The presence of lipocaic deficiency in these animals is indicated after five to six weeks by a decrease in the concentration of fat in the blood to approximately half of the

normal concentration, decrease in insulin requirement, decrease in dextrose excretion, loss of weight and appetite, impairment of liver function as evidenced by the bromsulphalein test and the finding of fatty accumulation in the liver as determined by laparotomy and biopsy. Lipocaic may be concluded to be present in a pancreas extract which when given to such animals restores the concentration of blood fat to the normal amount, restores the insulin requirement to the amount required immediately after operation, restores the average dextrose excretion, corrects the abnormality of liver function and removes the fatty accumulation in the liver, as determined by a second laparotomy and biopsy.

Wolffe has not presented this sort of evidence indicating the presence of lipocaic in his pancreas extract.

UREA INJECTIONS FOR WARTS

To the Editor:—It has come to my attention that a solution of urea has been used for injection beneath the base of ordinary warts on the hand which are incurable by any other treatment. Are there any references on the subject?

J. Dwight Wilson, M.D., Berkeley, Calif.

ANSWER.—The only reference found to this form of treatment is "The Use of Urea (Carbamide) in the Treatment of Warts (MacKay, E. M.: *Arch. Dermat. & Syph.* 41:736 [April] 1940). Based on the virucidal power of strong solutions of urea and their harmlessness in contact with human tissues, it was thought that the drug might be useful in the treatment of warts. Experimentation was begun by the inoculation into monkey skin of an extract of human warts in physiologic solution of sodium chloride. These injections were frequently followed by the growth of warts. An extract of warts made with a solution of urea did not cause warts in monkeys. With this as a basis, the treatment of human warts was undertaken, a 50 per cent sterile aqueous solution of urea being used. From 0.1 to 0.3 cc. of this solution was injected into the base of each wart, but not deeply. This caused pain, moderate in most instances.

The first six patients were all cured by the first injection. Of sixteen others treated by other physicians, eight were cured by one injection and several yielded to the second injection, but some of the patients resisted the treatment entirely. The cures resulted in from five to eighteen days after the injection. The author considers multiple warts more resistant than single ones. He did not treat plantar warts.

After beginning his investigation, the author discovered the report of Pietzsch in 1927, who used a method almost identical with MacKay's in the treatment of warts in horses. No reference to the use of his method in man was found.

ALCOHOL, ETHER AND ACETONE AS DISINFECTANTS

To the Editor:—What are the relative values of the following three agents when used as skin or wound antiseptics: 70 per cent alcohol by weight, ether or acetone? In this connection it is noted that acetone is often used as a base for many of the dye antiseptic solutions. I am unable to find any definite information as to the relative value of these three agents.

M.D., Virginia.

ANSWER.—Ethyl alcohol in 70 per cent solution by weight is an efficient skin disinfectant, especially when used with gauze friction for two or three minutes (Price, P. B.: Ethyl Alcohol as a Germicide, *Arch. Surg.* 38:528 [March] 1939). This action is independent of any detergent quality of the solution. Disadvantages of alcohol lie in the narrow range of its strongly germicidal concentrations and the bother of preparing and maintaining solutions exactly 70 per cent by weight. Alcohol is useful in cleaning and degerming cutaneous margins of wounds, but in wounds it is painful and useless if not harmful.

Ether is a prime fat solvent, but its detergent effect on surfaces is negated to a certain extent by rapid evaporation. An ether sponge may remove numbers of "transient" bacteria along with the grease and dirt. But ether rates low as a germicide. It is incapable of reducing the "resident" flora of the skin (Price, P. B.: Surgical Bacteriology and Technique, *THE JOURNAL*, Nov. 26, 1938, p. 1993). The routine use of ether as a step in preparation of the field of operation is of doubtful value. In recent freshly contaminated wounds, used with gentle friction, ether seems to have some value in preventing development of infection; it may thus improve the chances of successful primary closure of wounds. But in old chronically infected wounds it is ineffective. In this connection it is well to remember that ether precipitates proteins.

No dependable studies of the skin disinfectant action of acetone are known. But since this agent under optimal conditions in vitro is but weakly germicidal, it is not likely that the relatively small amounts present in various preparations of dyes have any disinfectant action per se. Acetone is usually added with the idea of increasing the penetrability of dyes into the skin. That it actually accomplishes this purpose is doubtful. A fact not generally appreciated is that the presence of water, even the small amounts contained in 95 per cent alcohol, causes acetone to lose its fat-solvent property.

RHEUMATIC HEART DISEASE EARLY AND LATE

To the Editor:—A patient who was in service during the World War has a record which states that on Nov. 20, 1918, he was found temporarily unfit for overseas service on account of endocarditis. Prior to his discharge on Jan. 9, 1919, examination showed him to be physically sound with no defects. At present, physical examination shows him to be suffering from mitral stenosis with regurgitation and cardiac dilatation. The question is: Would one suffering from endocarditis be likely to recover completely within the six or eight weeks period, or is it probable that the present cardiac condition is a result of the previous attacks?

M.D., Illinois.

ANSWER.—This case is an interesting example of the fact that one may find during active rheumatism in youth cardiac abnormalities which may regress or even apparently disappear entirely. There may be murmurs, particularly systolic at the apex and even middiastolic, as the result of temporary or subacute dilatation of the heart secondary to rheumatic myocarditis even before the valves are deformed. With the recovery from the acute rheumatism the heart size may return essentially to normal with the disappearance of murmurs, but continued or recurrent rheumatic infection over the years to come may result eventually in the development of real valvular deformity, especially mitral stenosis, which eventually becomes evident on examination.

This is the probability in the case referred to, but there is also the possibility that the second examination early in January 1919 might have overlooked evidence of heart involvement which was actually present at that time.

HYPOTHYROIDISM IN PREGNANCY

To the Editor:—What should be done for a pregnant woman who displays mild symptoms of hypothyroidism and possibly hypopituitarism? She is a tertipara four months pregnant. She was sterile for five years. Anterior pituitary extract was given because of the presence of an infantile uterus and of the sterility. Significant enlargement of the uterus occurred and she became pregnant and gave birth to a normal child. Pituitary medication was given up to the first month of pregnancy. About a year and a half later, with no further endocrine therapy, she gave birth to another child, but this child at from 3 to 4 months of age displayed definite signs of hypothyroidism (cretinism). This child is still receiving thyroid.

M.D., New York.

ANSWER.—Desiccated thyroid may be started at once and the minimum dose administered that will maintain the basal metabolism within normal limits. It would probably be safe to start with 1 grain (0.065 Gm.) of U. S. P. thyroid daily and give a little more or less, depending on the basal metabolism. It should be emphasized that the basal metabolism is elevated as much as from 25 to 30 per cent above normal in the last three months of pregnancy, making it necessary to determine the maintenance dose as well as possible in the first half of pregnancy. If animal experiments reflect the state of affairs in man, the administration of thyroid to mothers with hypothyroidism reduces the incidence of cretinism in the offspring. No pituitary extract should be given during pregnancy.

BRONCHIAL ASTHMA AND THYROIDECTOMY

To the Editor:—A woman aged 46 complains of bronchial asthma, which started three years ago about three months after a thyroidectomy. The patient gives no history of allergy other than the asthma, which she insists was in some way or other precipitated by her operation. She even asserts that she found in some newspaper health column reference to the fact that bronchial asthma may be caused or precipitated by thyroidectomy. She has been given cutaneous tests and been found sensitive to cattle hair and horse dander and was relieved by desensitization with these allergens. Is the relation between the operation and the onset of the asthma likely to be coincidental, or is it possible that the patient's theory is correct?

Walter Lewinnek, M.D., Mason City, Ill.

ANSWER.—There is no definite relationship between thyroidectomy and bronchial asthma. It is true that a substernal thyroid can cause wheezing by pressure on the trachea or on one of the main bronchi, in which case the wheezing would usually be found on the side of the pressure. True bronchial asthma, however, is bilateral and has no relationship to thyroid disease and thyroidectomy.

HYPERTROPHY OF GUMS FROM DILANTIN SODIUM

To the Editor:—A girl aged 20 years has had essential epilepsy since she was 15. There are petit and grand mal attacks. About twenty months ago I gave her four capsules of dilantin sodium every twenty-four hours. Previously large doses of phenobarbital did not control the attacks, but the dilantin sodium, taken with vitamin C, has been satisfactory, except for a gradually increasing hypertrophy of the gums. This condition has lately become so acute that I have had to stop the dilantin sodium. The attacks of epilepsy have almost immediately become acute again. I should appreciate any advice as to the treatment of the hypertrophy and suggestions as to the advisability of continuing the treatment with dilantin sodium. Is there anything new on the treatment of the gum condition? Is there danger of this condition not yielding to treatment if dilantin sodium is given regularly?

M.D., Georgia.

ANSWER.—Hypertrophy of the gums is a recognized complication of treatment with dilantin sodium in children. Recent investigations have shown that the process is entirely different from that seen in scurvy and that it bears no relationship to the vitamin C level. Aside from the appearance of the gums, the hypertrophy appears to do no harm, even when it persists over years. It is often preferable to the attacks.

It might be worth while to try substituting phenobarbital 0.1 to 0.2 Gm. daily for a similar amount of dilantin sodium. A vigorous outdoor life is often beneficial.

ABSENT KNEE JERKS IN DIABETES

To the Editor:—What is the basis for absent knee jerks in the diabetic?
 Samuel G. Slo-Bodkin, M.D., Brooklyn.

ANSWER.—The common cause of absent knee jerks in diabetes is neuritis (neuronitis). The explanation for its frequent occurrence in diabetes is not entirely clear except that it is in some way due to the effects of diabetes on the central nervous system. Other conditions responsible for absent reflexes may be present coincidentally.

SUBACUTE BACTERIAL ENDOCARDITIS

To the Editor:—1. Has there been any definite value in transfusion of blood from a patient who has recovered from Streptococcus viridans endocarditis? 2. Is a list of donors available? 3. By what criteria is it determined that one has recovered from subacute bacterial endocarditis? 4. Does recovery mean that the danger from embolism has passed? 5. Is the coronary artery the most likely site for embolism and is recovery possible?
 W. D. Bretz, M.D., Huntingburg, Ind.

ANSWER.—1. There has been a great deal of newspaper publicity implying that blood transfusions from a patient who has recovered from Streptococcus viridans endocarditis are curative. There is no adequate evidence that such transfusions have resulted in cure.

2. So far as known, no list of donors is available.

3. Many patients experience a period of arrest, but only after two or three years of freedom from fever and absence of other symptoms can a patient be considered to have recovered.

4. There is but little danger of embolism after a three year period of freedom from all symptoms, although it may occur.

5. The coronary artery is not a common site of embolism, although signs of small emboli in the heart muscle have been reported post mortem not infrequently. Such emboli are not often fatal.

"BABYKIN" BOTTLE CONTAINER

To the Editor:—Lately several mothers have asked me about "Babykin" Scientific Container, made by Lockwood Products, Chicago. This container is supposed to keep a baby's formula just the right temperature for a 2 a. m. feeding, even though placed in the "babykin" at 10 p. m. We have always known that placing warm or hot milk into a vacuum bottle causes an abnormally large number of bacteria to grow and the formula to become sour within a few hours, usually producing a gastrointestinal disturbance if the baby takes such a feeding. Is there any difference between the "Babykin" and the regular vacuum bottle?

Leonard F. Bender, M.D., Philadelphia.

ANSWER.—There is some difference between the "Babykin" and the regular vacuum bottle in that liquids are put directly into the vacuum bottle while the "Babykin" is meant only to hold the baby's milk, which is stoppered in the regular baby's bottle. Milk put directly into the vacuum bottle may be contaminated by bacteria on the cork and within the bottle itself. It is not possible to sterilize the vacuum bottle, since heating will break it. Thus, milk put into a vacuum bottle and kept

warm will probably sour within a short time. However, the milk in the baby's bottle which has been boiled and sterilized will not sour within a period of twelve hours or longer. The use of the "Babykin" for a reasonable period appears to be safe.

INJECTION OF TRYPSIN IN MAN

To the Editor:—Can a dilute sterile solution of trypsin (the enzyme) be injected subcutaneously into a human being without ill effects? The enzyme in the solution is active. Maurice Vaisberg, M.D., New York.

ANSWER.—Trypsin is extremely toxic and gives rise to symptoms resembling those of snake venoms. (Rocha e Silva, M.: *Arch. f. exper. Path. u. Pharmacol.* 194:335, 1940).

VACCINES FOR TYPHUS

To the Editor:—Is there a serum or vaccine, not experimental, for typhus fever that is now known to be effective? Our board of health is using one and I have not used it as my reports say it is not yet of proved worth. H. A. Geitz, M.D., Monterrey, Mexico.

ANSWER.—Several vaccines prepared from tissue cultures of the specific rickettsia of typhus fever are being tried experimentally. An extensive experiment is being carried out in Europe at the present time but as yet no serum or vaccine against typhus possesses proved value.

X-RAY THERAPY FOR CARCINOMA OF PANCREAS

To the Editor:—Is x-ray treatment of any value for carcinoma of the pancreas? In the case I have in mind an anastomosis between the gall-bladder and the jejunum has been done to relieve the biliary obstruction.

M.D., New York.

ANSWER.—There is no authentic evidence available to indicate that x-ray therapy is of any value for carcinoma of the pancreas.

AMBULATORY AUTOMATISM OR FUGUE

To the Editor:—The inquiry from a physician in New York in The Journal, August 10, concerning his compulsive movements and the answer suggesting a psychic epileptic equivalent interests me because it has three unusual features: 1. It occurs only at night. 2. It does not occur at night except when he goes to his office. 3. His fugue consists largely of this motor component without any accompanying dreamy state or amnesia. The length of the attack and its sudden stoppage when the physician leaves for home makes one believe there is a neurotic component. The answer considers this possibility. I wonder, therefore, why the suggestion was made for 1 Gm. of sodium bromide to be taken three times daily. May I also comment on the references. The first should be Oppenheim and not Oppenheimer. This reference is to Bruce's English translation of a rather old book which I first translated forty years ago for J. B. Lippincott & Co. The best review of the subject today is that by S. A. Kinnier Wilson, "Modern Problems in Neurology" (1926), published by Williams and Wilkins, Baltimore. Gower's book on "Epileptic Equivalents," although printed many years ago, is still the best monograph that has been written on this subject.

Edward E. Mayer, M.D., Pittsburgh.

POLIOMYELITIS AND TONSILLECTOMY

To the Editor:—In Queries and Minor Notes (The Journal, September 7, p. 877) the first reply to the question on poliomyelitis and tonsillectomy refers to a group of cases of the bulbar type reported by Aycock and Luther (New England J. Med. 200:164 [Jan. 24] 1929) as having followed tonsillectomy "by seventeen to eighteen days, an interval corresponding with the incubation period of the disease." The interval between tonsillectomy and onset of the disease in this group of cases was actually seven to eighteen days.

A second reply to the question expresses doubt as to whether tonsillectomy is a predisposing factor to infantile paralysis because of the great number of such operations performed in the fall of the year "without any apparent material increase in the number of cases of infantile paralysis." While we have seen three bulbar cases following tonsillectomy in the practice of one physician within a month (175 tonsillectomies), it is true that few or no such cases may be encountered in even a large series of tonsillectomies; but any sizable study of poliomyelitis will show a greater proportion of cases of the bulbar type following tonsillectomy by a specific interval than would occur by coincidence. For example, Eley and Flake (J. Pediat. 13:63 [July] 1938) reported that eight (2.07 per cent) of 287 patients with spinal poliomyelitis admitted to the Children's Hospital, Boston, had had tonsillectomy within a month, whereas seventeen (12.98 per cent) of 131 with the bulbar type admitted during the same period had had tonsillectomy within a month. Of greater significance was the time interval between tonsillectomy and onset of the disease in the two groups. The eight spinal cases followed tonsillectomy by seven to thirty days (random), whereas all seventeen of the bulbar cases occurred between the tenth and twentieth days following tonsillectomy. It should be noted that one patient had only adenoidectomy.

While it cannot be said that season per se constitutes a contraindication to tonsillectomy, it is clear that the avoidance of this operation where poliomyelitis is prevalent undoubtedly would prevent the occurrence of a number of cases of this distressing and highly fatal form of the disease each year.

W. Lloyd Aycock, M.D., Boston.

Harvard Infantile Paralysis Commission.

Medical Examinations and Licensure

COMING EXAMINATIONS

BOARDS OF MEDICAL EXAMINERS BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Examinations of boards of medical examiners and boards of examiners in the basic sciences were published in *THE JOURNAL*, September 28, page 1123.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: Parts I and II. Various centers, February. Part III. Baltimore and New York during October and Boston during November. Exec. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

EXAMINING BOARDS IN SPECIALTIES

AMERICAN BOARD OF ANESTHESIOLOGY: *Written*. Various centers, Feb. 20. Final date for filing application is December 21. *Oral*. Cleveland, May 31-June 1. Final date for filing application is April 1. Sec., Dr. Paul M. Wood, 745 Fifth Ave., New York.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Oral*. Chicago, Dec. 6-7. Applications for Group A must be on file not later than Nov. 1. Sec., Dr. C. Guy Lane, 416 Marlboro St., Boston.

AMERICAN BOARD OF INTERNAL MEDICINE: *Written*. Parts 1-A and 1-B, Feb. 17. Final date for filing application is Jan. 1. Sec., Dr. William S. Middleton, 1301 University Ave., Madison, Wis.

AMERICAN BOARD OF NEUROLOGICAL SURGERY: Chicago, Oct. 18-19. Sec., Dr. R. Glen Spurling, 404 Brown Bldg., Louisville, Ky.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: Part I Group B examinations, locally, Jan. 4, 1941, at 2:00 P. M. Final date for filing application is Oct. 5. Part II, Groups A and B, Cleveland, Ohio, June 1941, immediately prior to opening of A. M. A. meeting. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY: *Oral*. Cleveland, Oct. 5. *Written*. Various centers, March 8. *The only written examination during 1941*. Applications must be on file not later than Dec. 1. Sec., Dr. John Green, 6830 Waterman Ave., St. Louis.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY: *Oral and written*. New Orleans, January 1941. Final date for filing application is November 15. Sec., Dr. Fremont A. Chandler, 6 N. Michigan Ave., Chicago.

AMERICAN BOARD OF PEDIATRICS: New York, March 30-31, following the Region I meeting of the American Academy of Pediatrics. Chicago, May 18, following the Region III meeting of the American Academy of Pediatrics. Sec., Dr. C. A. Aldrich, 723 Elm St., Winnetka, Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY: *Oral*. New York, December 18-19. Final date for filing application is October 10. Sec., Dr. Walter Freeman, 1028 Connecticut Ave. N.W., Washington, D. C.

AMERICAN BOARD OF UROLOGY: *Oral and written*. Chicago, February 1941. Applications must be on file not later than Oct. 15. Sec., Dr. Gilbert J. Thomas, 1009 Nicollet Ave., Minneapolis.

Missouri June Report

Dr. Harry F. Parker, secretary, State Board of Health of Missouri, reports the written examination held for medical licensure at St. Louis, June 6-8, 1940. The examination covered fifteen subjects. An average of 75 per cent was required to pass. One hundred and sixty-one candidates were examined, all of whom passed. Twelve physicians were licensed to practice medicine by reciprocity. The following schools were represented:

Book Notices

The Australian Army Medical Services in the War of 1914-1918. Volume II: The Western Front. By Colonel A. G. Butler, D.S.O., V.D., B.A. Cloth. Price, 21s. Pp. 1,010, with 212 illustrations. Canberra: Australian War Memorial, 1940.

This volume is concerned chiefly with the operations of the Australian army medical service on the western front, 1914-1918. The book is divided into three sections and fourteen appendixes.

Section I is a narrative of those aspects and events in which the Australian forces directly participated until the end of 1917. The course of the fighting is followed chronologically from the preliminary sorties and feints leading up to the battle of the Somme until the third battle of Ypres. The battle of Cambrai, big in its import and omen if slight in its direct effects, completed the old and points the new phase of the war.

Section II examines, from an objective service standpoint, the fundamental problems of the prevention of disease and of the rescue, repair and return to duty of casualties. Accordingly, the chapters of this section follow the course of a casualty from the regimental aid post through the various stages and levels of transport and treatment in the field, at the expeditionary base and at home, to the command depots and overseas training brigade. A final chapter of the section examines the technic of disease prevention.

Section III resumes the narrative of the experiences of the Australian army medical service on the western front. The successive blows in the British advance up the Somme to the Hindenburg line are described. The dual task facing the Australian medical service is clearly brought out. Within eight weeks it was necessary to deal with one seventh of the total battle casualties and to sustain the chief part in the problem of maintaining the fighting formations at a strength adequate for these stupendous tasks—and this in the face not only of casualties but of pandemic influenza. Not the least significant feature of the Australian army medical service in the war is revealed in the fact that, of the effectives that reached the front, no less than 60 per cent were recovered men.

As related in this volume, the salient lessons that seem to emerge from the Australian experience in the evacuation of wounded in the great war may be thus summed up: 1. In any great battle a proportion—which may be estimated at some 2 to 5 per cent—of all casualties other than from gassing will, if their lives are to be saved, require special arrangements for insuring early operation or for effective first aid at a field or mobile hospital. 2. For the rest, success in evacuation is in a great measure determined by the exact and early discrimination of stretcher cases, "sitters" and "walking wounded" and the making of special and adequate arrangements for the transport and treatment of each class. 3. The basic principle, to insure successful evacuation under all conditions and every combination of circumstance, the medical scheme must adapt its arrangements to the fundamental constants, physical, physiologic and pathologic, which lie, and will always lie, behind the particular problems of all types of warfare and of every battle.

This volume has mirrored truly the interplay of the constant factors that compose the medical problem—time and distance, mass and movement, human powers and human limitations—which are common to any type of warfare. Only one feature prevents this volume from being an intensely interesting and readable work. Too many abbreviations cause too many interruptions to those unfamiliar with the British medical evacuation system; otherwise this volume may be recommended to any one studying or contemplating active medical field service as a mine of exact information.

Localisations viscérales et aspects chirurgicaux des brucelloses. Par R. Michel-Béchet, associé national de l'Académie de chirurgie. Avec la collaboration de MM. R. Pulg et P. Charvet. Préface du Pr B. Cunéo. Paper. Price, \$1.15. Pp. 168, with 22 illustrations. Paris: Masson & Cie, 1939

It is gratifying to American investigators of human brucellosis in its varied forms to find in so valuable a book as that of Michel-Béchet and his collaborators that these French authors have discarded the former designations of the disease—Malta, or undulant, fever—names which were probably to some extent responsible for the failure to recognize phases of the disease which occur without significant rises in temperature. The authors emphasize that there is no definite pattern of brucellosis. Nothing is more fantastic, they say, than the evolution of this disease. The onset may be insidious, or an attack of indigestion suggests intestinal grip; or pain in the joints suggests rheumatism, and it is only after the attacks have been repeated a few times that one thinks of brucellosis.

Four cardinal signs are mentioned as characteristic of the septicemic phase of brucellosis: temperature, pain, perspiration and weakness. The rises in temperature may occur in waves (which suggested the name "undulant fever"). But the undulating temperature curve is not a constant feature. It may vary in intensity; the undulations may proceed without intervals; after weeks or months of apparent health a new wave may appear. The French have a name for it: "lunatic fever." There is an uncertainty as to whether brucellosis can occur without fever, because in some cases observations of temperature are not made in the initial period, which may be more or less ignored. The afebrile form of the disease is encountered especially in children. The painful manifestations of brucellosis are extremely varied. They may involve joints, nerves or subcutaneous tissues. Asthenia is an important feature. It may deprive the patient of all energy or desire for a normal life, persisting for a long time without accompanying fever, pain or perspiration. A psychic factor may be involved in the asthenia. The patient who has been disabled for a long time, discouraged by persistent pain and disappointed with the failures of therapy may fall into a kind of apathetic resignation. Sometimes after long periods of asthenia there will be a relapse, with localization of the infection.

Orchitis occurs in about 20 per cent of cases. The genital organs of the female are less frequently affected. Although in domestic animals abortion is a unique manifestation of brucellosis, in women brucellar infection seems to have no more effect on gestation than any other septicemia. Anemia with leukopenia and monocytosis with polymorphonuclear leukocytes falling to 40 or 50 or even as low as 20 per cent form a characteristic blood picture. Epistaxis is a frequent symptom. Other symptoms observed are indigestion with stubborn constipation, anorexia, diarrhea in severe cases, enlarged liver and, less frequently, enlarged spleen. The heart and kidneys are rarely affected. These symptoms characterize the average case. The authors emphasize, however, that the disease cannot be codified. The book describes other manifestations which occur irregularly and are of little diagnostic value.

Convalescence is prolonged. After apparent recovery a new wave of fever may occur with or without a return of the original symptoms or with painful osseous or nervous complications. Brucellosis presents an infinite variety of evolutions which may be violent or mild. In certain parts of France the disease is a veritable social scourge. Whether there is ever complete recovery from brucellosis is a question the authors raise without answering, except by citing cases in which there were recurrences long after apparent recovery.

The authors found it difficult to estimate the percentage of cases of brucellosis in which complications develop because, as a rule, patients with uncomplicated brucellosis do not enter the hospital. They state, however, that in 80 per cent of cases with localization of the infection the localization was preceded by a recognizable septicemic phase of the disease.

Brucellar hepatitis is the most frequent localization. It can be the only manifestation of the infection. At the time of the third or fourth wave of fever the liver may increase in volume and become painful; diverse hemorrhages may appear—bleeding gums or purpura especially on the lower limbs, associated or

not with edema. These symptoms and the various complications which may be associated with them are discussed in detail, with case reports. Brucellar infection can invade the biliary tract, causing angiocholitis or cholecystitis. The authors believe they are the first to report that brucellar infection may be the cause of biliary lithiasis.

Nervous complications are second in order of frequency. They resemble the nervous symptoms of syphilis more closely than those of any other infectious disease. The different aspects of neurobrucellosis, with detailed discussion and case reports, are enumerated: (1) the encephalitic syndrome, (2) the medullary syndrome, (3) the peripheral syndrome, (4) the meningeal syndrome. Any one of them may be acute or chronic. A chapter is devoted to respiratory complications. Brucellar laryngitis, tracheobronchitis, pulmonary congestion all resemble tuberculous infections. Errors in diagnosis are frequent. In a section of the book entitled "Surgical Aspects of Brucellosis" are included visceral, osseous and osteo-articular localizations, with separate chapters devoted to the complications which are of especial interest—facial lesions, osteoperiostitis, osteo-arthritis, coxitis, spondylitis.

The dry black facial lesions have a marked predilection for the area over the body of the jaw in front of the masseter. They may be bilateral. The topography and behavior of these lesions are so precise that a retrospective diagnosis of brucellosis may sometimes be made in cases in which the correct diagnosis was missed. Cases in which the facial lesions develop are usually severe and end fatally.

Osteoperiostitis may develop in the course of the second or third wave of fever or early in convalescence. In some cases it is the only manifestation of the disease.

Osteo-arthritis seems to occur most frequently in young people. Localization in the hip is most frequent, followed by the knee, the elbow, the shoulder and the sacro-iliac joints. The inflammatory lesions may be acute or chronic. They usually develop during convalescence and accompany a recurring septicemic episode. But they can be the only manifestation of a relapse with no rise in temperature or they may mark the beginning of the disease. In such cases errors of diagnosis can easily be made. Clinically the osteo-arthritis of brucellosis may be subacute or chronic, resembling tuberculosis; or acute, resembling a gonococcal infection. The pain may be violent. As a rule, however, there is an absence of suppuration and ankylosis.

Reports of three cases of coxitis are given. In one of them there had been no fever for three years previous to the development of the painful joint; in one there was no other manifestation of brucellosis; the third case was extremely acute, with the temperature rising to 40 C. (104 F.).

Under the term spondylitis the authors designate all localizations in the vertebral column detectable by x-ray examination, whether osseous or osteo-articular, acute or subacute, excluding the simple vertebral reactions of brucellar septicemia, which are almost constant. The subject is treated extensively, with many reproductions of roentgenograms. Spondylitis occurs much more frequently in men than in women; it occurs especially in patients past 40. The lumbar region is most frequently affected. Sometimes spondylitis develops long after the septicemic episode; it may be unaccompanied by an elevation of temperature. The patient may be incapacitated six or eight months or more.

Brucellosis is fatal in only 2 to 4 per cent of cases. Its seriousness lies in the length of evolution, in the painful manifestations and in the persistent weakness it leaves. It ruins poor people.

The responsibility which should be assumed for veterinarians, dairymen and others who are infected in line of duty is discussed, together with the difficulties involved. In the case of slaughterhouse workmen in cities, where the foyers of infection is known, the difficulties of authentication are relatively slight. On the contrary, in rural districts where there is the possibility of contracting infection from food or various objects soiled by infected animals, it would be almost impossible to prove that the infection was contracted in line of duty.

The authors discuss the various methods of treating brucellosis under (1) anti-infectious therapy, chemical or biologic, and (2) symptomatic therapy. They do not heartily endorse any of the

proposed methods of anti-infectious therapy. On account of the irregular evolution of the disease they are always skeptical, they say, in reading statistics of therapeutic successes. Nourishment should be substantial. The authors insist that even patients with high temperature must take as much nourishment as possible. Each physician must judge for himself the best medication for the particular manifestations which he finds: for example, vitamin B for nervous complications, soporifics for patients troubled with insomnia.

Experimental Poliomyelitis. I: A Critical Review of the Literature with Special Reference to the Use of the Neutralization Test in Immunological Studies. II: The Neutralization Test. A Study of Some Factors Involved in the Neutralizing Action of Immune Serum Against Poliomyelitis Virus. By Morris Schaeffer, Ph.D., and Ralph S. Muckenfuss, M.D. Department of Health. Bureau of Laboratories, New York, N. Y. Published under the auspices of The National Foundation for Infantile Paralysis. Paper. Pp. 158. Lancaster, Pa.: Science Press Printing Company, 1940.

The authors describe their extended experience with neutralization tests in experimental poliomyelitis, which in large part consisted in 440 tests with one pool of virus and one pool of human convalescent serums. On the average, the outcome of one test out of six was irregular according to Aycock's analysis of the data, while one test out of four was irregular as judged by the criteria of Schaeffer and Muckenfuss. Thus they regard the present neutralization test as not practical for quantitative purposes and they consider that all attempts to define a minimal infective dose of virus have been unsuccessful. They reason that general epidemiologic principles but not specific immunologic problems have been elucidated by the test. They accept the widespread distribution of humoral neutralizing substances in man and a general immunologic relationship between all strains of poliomyelitic virus. They regard as unsettled the existence of specific immunologic differences among strains and they believe that a relation between protection against infection and the presence of neutralizing bodies in the blood does not hold for individuals either in the experimental or in the natural disease. In this last view they are supported by other authorities, but it is not clear that this aspect of the problem has been studied adequately with the proper epidemic strain. The original experiments presented in part II were planned to bring to light factors which might eliminate irregular results. One supply of virus was used throughout. This consisted of a glycerinated pool of spinal cords from fifty monkeys. As the experiments progressed two leads were uncovered. One concerned the use of a short needle (one fourth inch) for intracerebral inoculation and the other was the substitution of the cisterna magna for the cerebral hemisphere to receive the inoculation. It might be noted in passing that the aging of the pool of virus might have been a factor of importance also. Emphasis in the text is specialized and the book will be of most value to those interested in the technical features of the neutralization test. The bibliography contains 289 titles.

Differential Diagnosis in Internal Medicine. By Prof. Dr. Med. O. Naegeli. Authorized English translation by Simon B. Spilberg, M.D., Head of the Department of Internal Medicine, Mount Sinai Hospital, Milwaukee, Wisconsin. Cloth. Price, \$10. Pp. 726, with 162 illustrations. Chicago: S. B. Debour, Publishers, 1940.

This is a good book, particularly for those specialists of internal medicine who have had sufficient background and training to appreciate symptom complexes rather than general descriptions of diseases. The author presumes that the reader is well acquainted with disease pictures and particularly with hematology and emphasizes in his preface that the importance of hematology in differential diagnosis has not been sufficiently appreciated. Throughout the entire book it is therefore noticeable that the author directs attention to the possible significance of the blood as a differential diagnostic aid. The chapters on the anemias, hemorrhagic diathesis, leukemia and allied diseases are exceedingly well presented. What is especially important is the presentation of clinical observations which have been gained only through years of experience. Such facts are most valuable to the physician in differentiating the questionable cases. An excellent illustration of this is the chapter on special differential diagnosis of pernicious anemia. It is regrettable that in these chapters there are not more illustrations of blood smears. Otherwise, however, the entire book is well illustrated with appropriate diagrams, photographs

and brief but carefully selected case histories. The chapter on the symptom complex of a large spleen with gastrointestinal hemorrhage, which deals especially with chronic thrombosis of the portal vein and of the splenic vein, is commendable since the clinical picture is in general too little known but is highly characteristic. The subjects presented cover the entire field of internal medicine and diseases of the nervous system. Special comment should be made of such chapters as those on the differential diagnostic significance of electrocardiographic observations, the differential diagnosis of pains in the back and flank caused by root sciatica, lumbago, disorders of the spine, prostatic diseases and polyneuritis, the differential diagnosis of psychoneurosis from organic disease especially in insurance compensation, psychoneuroses, demand neuroses, vasomotor neuroses, encephalosis post-traumatica after skull injury and gross organic traumatic diseases of the brain. Probably the weakest chapters are those dealing with hypertension and nephritis. The book is exceedingly well printed but the binding could be improved. The translator has performed a creditable task in presenting this book to the medical profession.

The Badianus Manuscript (Codex Barberini, Latin 241) Vatican Library: An Aztec Herbal of 1552. Introduction, translation and annotations by Emily Walcott Emmart. With a foreword by Henry E. Sigerist. Cloth. Price, \$7.50. Pp. 341, with 118 plates. Baltimore: Johns Hopkins Press; London: Oxford University Press, 1940.

One of the most interesting books that have appeared dealing with the early history of medicine on the Western Continent is the reproduction of the Badianus Manuscript. The original of this volume, which appeared in 1552, is in the Vatican Library. It is an Aztec herbal and is not only the earliest complete Mexican medical treatise which is known but is also the only medical text known to be the work of the Aztec Indians. The authors of the herbal were two Indians, Martinus de la Cruz, the writer of the text, and Juannes Badianus, "reader in Latin," who translated it into that language. Both men were at the College of Santa Cruz at Tlaltilulco. The original volume, of which this is a facsimile, is a small book bound in sixteenth century crimson velvet which shows the imprint of metal clasps. The Latin text of the original has been translated for this facsimile by Dr. Emily Walcott Emmart, who has included in the book an extensive and interesting introduction describing the original volume and its history as far as it is known. This introduction also discusses the colors used in the original illustrations, the nature of the pigments employed and their symbolism, together with a chapter on mythology and materia medica as they are represented in the volume. Finally there is also a description of Aztec herb gardens.

In this volume are reproduced in color the 118 pages of the herbal showing 184 illustrations of native plants and trees which were employed by the Aztecs in the practice of the healing art. These illustrations are of great interest, as they are the earliest known pictures of American botany. They are reproduced from photographs taken in the Vatican Library, the beautiful water color reproductions being the work of Madame Marie Thérèse Missonnier-Vuillemin, niece of Eugene, Cardinal Tisserant, prefect of the Vatican Library. The colors in the original paintings have been admirably reproduced by the printer Mr. A. B. Hoen. Many of the plants are difficult of recognition, as they are all drawn of one size and are lacking in perspective. As the translator, Badianus, did not know the Latin botanic names for the plants they are all labeled with their Indian names, so that the plants are in many cases hard to identify. Under each picture is the name of the disease or condition for which the plant is to be used and this is followed by a brief description of the way it is to be employed.

The work is divided into different chapters, each one treating of a certain class of disorders. For example, chapter I treats of "the head, boils, dandruff, scabies, falling hair, lacerations or fractures of the head"; chapter II of the eyes; chapter III of the ears; chapter IV of "coryza, medicine to be instilled into the nose, blood herb," and so on. Besides these and many other medical conditions for the treatment of which remedies are provided, directions are given for other states which perhaps may be considered as nonmedical. Among these is the "herb for lassitude" and "trees and flowers for the fatigue of

those administering the government and holding public office"; for the latter use some fifty drugs are mentioned, including the brains and bile of several animals, among them the coyote and the skunk. Some of the references to diseases are quite good, as for instance the discussion of the treatment of fevers, in which the main symptoms of the condition are well listed.

Naturally the remedies mentioned are by no means confined to the vegetable kingdom, as a large number of animal and mineral products are also advised. Among these as illustrations may be mentioned a purple or white stone from the stomach of a swallow, inhalation of the odor of burning hair, pebbles collected from brooks, an Indian kite and dove ground in water, and a burned heart of a stag ground in water.

Enough has been said to indicate the general character of this interesting work. It should be pointed out that the publication of the facsimile has been made possible only through the cooperation and support of the Smithsonian Institution, various garden clubs, which were interested in it on account of its being the earliest herbal of the New World, and finally a number of individuals who contributed generously to the project.

The facsimile volume is a fine example of book making and reflects great credit on the Johns Hopkins Press and the printers, A. Hoen & Co., Inc.

Principles of Hematology with 104 Illustrative Cases. By Russell L. Haden, M.A., M.D., Chief of the Medical Division of the Cleveland Clinic, Cleveland. Second edition. Cloth. Price, \$4.50. Pp. 362, with 167 illustrations. Philadelphia: Lea & Febiger, 1940.

The appearance of the second edition of this excellent book one year after the first attests its popularity. There are fourteen additional pages, and more than twelve illustrations have been added. The material is presented in terms of the physiology of blood and its pathologic variation. Morphology, although emphasized, is used to describe processes and mechanisms rather than names of structures. Haden feels that "the average physician should not attempt to interpret conditions which puzzle even an experienced student of the blood" and so has omitted the technic of supravital staining and biopsy and puncture of the bone marrow. The details of technical methods of blood examination are well presented, and new and helpful features have been added. The clinical features of the diseases are brought out as the "mechanism" of the disease, and the classic features are elaborated in the case reports. Therapy is treated in the same way. The 104 cases described, if carefully studied, would constitute an excellent form of postgraduate review for the student of hematology. The photographs are unusually good, many features being brought out in black and white with the same degree of clearness as some colored pictures. The diagrams in chapters 8 and 9 illustrating the formation, circulation and destruction of red and white blood cells in various conditions are nonmedical in character and probably would be of more value to the lay student than to the average physician. It is quite possible that some hematologists will take issue with the terminology and classifications, but hematology has not yet reached the stage when differences of point of view or nomenclature necessarily mean that one author is correct and another one wrong. The book is the best introduction to hematology that is available to medical students or practitioners and, because of its excellence and simplicity, will serve to standardize many variable features which now confuse both patient and physician.

Thirty-Seventh Annual Report 1938-1940 of the Imperial Cancer Research Fund. Founded under the direction of the Royal College of Physicians of London and the Royal College of Surgeons of England, 1902. Incorporated by Royal Charter, 1939. Paper. Pp. 43. London: Royal College of Surgeons, 1940.

Gye, director of the Imperial Cancer Research Fund, reports that a large part of the cancer research concerns the induction of malignant new growths by application of pure chemical substances and points out that this aspect of carcinogenesis has occupied the attention of the scientific staff of the fund for several years. Pullinger has found that polycyclic hydrocarbons which have the property of inducing cancer evoke, on the second to the fourth day after application, a reaction which is characteristic and may be specific. The chemically related hydrocarbons which do not induce cancer formation do not evoke the reaction. Crabtree's experiments indicate that substances with

the biochemical property of inhibiting cell glycolysis can, under different experimental conditions, either retard or accelerate the rate of induction of tumors by carcinogenic hydrocarbons.

The original observations of Cramer and Horning that brown degeneration of the adrenals occurs in mice which have been subjected to prolonged treatment with estrogen have been confirmed by Burrows, Lacassagne and Dobrovolskaia-Zawadskaia. Subsequent research on more extensive material, on many inbred strains of mice of high, medium, low or no cancer incidence, both by Cramer and Horning and by Dobrovolskaia-Zawadskaia, has shown that brown degeneration is not an invariable lesion present in cases of mammary cancer and that it is merely incidental to the physiologic changes which are brought about by excessive estrogenization.

Ludford has been interested in the leukocytes and macrophages which infiltrate tumors in vivo in relation to malignant growth. Leukocytes and macrophages may stimulate the proteolytic activity of the malignant cells and this might be expected to facilitate invasion of normal tissues. It is conceivable that a very intense stimulation of the proteolytic activity of malignant cells might result in a breakdown of the connective tissue framework of a tumor and bring about such a disorganization of its growth as to cause regression. Ludford has carried out experiments to explore this possibility.

Foulds is preparing a report on spontaneous fowl tumors. Two spontaneous sarcomas have been transmitted by filtrates of the original tumors. This is apparently the first recorded example of transmission of a spontaneous sarcoma by filtrate. Experiments with the nonfiltrable dibenzanthracene fowl sarcoma RFD2 by Foulds and Dmochowski indicate that there are at least two antigenic substances common to the nonfiltrable RFD2 and the filtrable Rous sarcoma and that the anti-RFD2 serums contain an antibody which reacts with the Rous tumor virus which has been repeatedly washed to remove extraneous fowl protein. The report contains a discussion of the experiments with the Shope rabbit fibroma. Knox, studying the desiccation of tissues, has achieved great improvement in the activity and the reliability of dried material by attention to the technic and principles of desiccation. He has also carried out experiments designed to analyze the nature of the filtrable agent of fowl sarcomas by feeding it as far as possible from fowl protein.

The Blood Picture in Hemorrhagic Anemia. By Jane M. Leichsenring and Alice Blester with the collaboration of Hortense Hönig Delnard et al., Division of Home Economics, University of Minnesota, Agricultural Experiment Station, Technical Bulletin 139. Paper. Pp. 120. St. Paul, Minn., 1939.

This presents, according to the authors, "a comprehensive study of blood changes occurring in hemorrhagic anemia induced in dogs maintained on a synthetic diet." The bulletin contains a large amount of data carefully obtained and presented in great detail. Physical measurements include blood volume measurements expressed in terms of cubic centimeters per kilogram of body weight; erythrocyte and leukocyte counts; determination of the hemoglobin, and measurement of the cell diameters and mean corpuscular volume. Chemical measurements include the oxygen capacity; total amino acid, nonprotein and urea nitrogen; preformed creatinine; calcium and phosphorus, and plasma protein, with albumin and globulin partition. The data and discussions are presented with regard to the three portions of the blood, the cells, the plasma and finally the whole blood and are based on the results of short and long time experiments. As a result of these experiments it is pointed out that "judgment of an individual's condition, based on hemoglobin level, red cell count or red cell hematocrit in the very early stages of recovery (after hemorrhage) would give an erroneous conception and create a false sense of security." The application of their results to the results of both acute and chronic hemorrhage in man is discussed in some detail and the similarity between the blood picture in dogs made anemic by hemorrhage and that observed in idiopathic hypochromic anemia of man leads to the suggestion that the "latter type is frequently the result of hemorrhage." The material presented together with a large bibliography makes the bulletin invaluable for those who may undertake experimental work on the blood of dogs, although no substantial contributions applicable to the anemias of man have been made.

Traité d'ophtalmologie. Publié sous les auspices de la Société française d'ophtalmologie. Par MM. P. Baillart, Ch. Coutela, E. Redslob, E. Velter. René Onfray: Secrétaire général. Tome VIII: Thérapeutique médicale, Hygiène, médecine légale, ophtalmologie des pays chauds, ophtalmologie comparée, déontologie. Par M.M. R. Bonnardel et al. Cloth. Price, \$10.50. Pp. 1,003, with 164 illustrations. Paris: Masson & Cie, 1939.

In view of what the French have had to undergo for the past year, they deserve enormous credit for the appearance on time of the eight volume treatise on ophthalmology. The preceding seven volumes have been reviewed in these columns and this last volume conforms to the others in physical characteristics. The material here is diverse and in many instances treated in a short chapter of only two or three pages, so that a general compilation will have to suffice, as follows: medical therapeutics of the eye, ocular hygiene, legal medicine, ophthalmology in the torrid countries, comparative ophthalmology and ophthalmic deontology, which latter term Webster defines as "the ethics of duty." The authors responsible for these chapters are Bonnardel of Paris, Brion of Lyons, Caillaud of Orléans, Cantonnet of Paris, Chappé of Paris, Cosse of Tours, Coutela of Paris, Gunsett of Strasbourg, Haas of Paris, Liegard of Paris, Margerin of Paris, Monthus of Paris, Pesma of Bordeaux, Plicque of Paris, Reiss of Strasbourg, Robin of Alfort and Toulant of Algiers. The entire volume is concluded with a comprehensive index of all eight volumes. The entire work is worth while. It is only natural that American ophthalmologists will disagree in many minor points and will be unable to subscribe to some of the surgical and therapeutic measures advocated. On the whole, the work is thorough, well written and well illustrated and contains an adequate international bibliography. This is without doubt the last large bit of work that will appear from France for many a year and fortunately it is one of which the French may well be proud.

The Compleat Pediatrician: Practical, Diagnostic, Therapeutic and Preventive Pediatrics for the Use of Medical Students, Internes, General Practitioners, and Pediatricists. By Wilburt C. Davison, M.D., D.Sc., M.D., Professor of Pediatrics, Duke University School of Medicine, Durham. (Adaptation of the Title Page of The Compleat Angler by Izaak Walton, 1653.) Third edition. Cloth. Price, \$3.75. Pp. 256. Durham, N. C.: Duke University Press, 1940.

This edition of the Compleat Pediatrician will be gratefully received by the many users and admirers of the first two editions. After one has acquired the habit of relying on this practical volume containing in such concise form a wealth of pediatric information as diagnosis, therapeutics, preventive methods, information on feeding diets and nutrition, laboratory tests, and other valuable facts necessary for the pediatrician's armamentariums, each new edition is eagerly received. The present edition has been brought down to date and contains the advances in therapeutics and procedures developed in the past several years; the newer advances in the recognition of vitamin deficiencies and therapeutics are excellently presented, as is the newer knowledge of chemotherapy with special regard to the use of sulfanilamide, sulfapyridine and sulfathiazole. The volume is thin and flexible and should fit into the general practitioner's bag. The younger pediatrician starting to practice will do well to purchase a bag in which this valuable reference book will fit. An experienced pediatrician will find great aid and comfort in frequently referring to the facts in this volume which have slipped from his memory and which can be quickly and accurately referred to in the Compleat Pediatrician.

Cyclopropane Anesthesia. By Benjamin Howard Robbins, B.A., M.S., M.D., Associate Professor of Pharmacology, Vanderbilt University School of Medicine, Nashville, Tenn. Cloth. Price, \$3. Pp. 175, with 40 illustrations. Baltimore: Williams & Wilkins Company, 1940.

This book represents a review of the literature on cyclopropane as an anesthetic agent. The physiologic and chemical properties of cyclopropane are presented, as are also the concentrations required for anesthesia based on accurate determinations of the amount of cyclopropane in the patient's blood. The author's results are compared to the results of others. The effect of cyclopropane on the various systems of the body is considered—the circulatory system, with special emphasis on the effect of the agent on the heart, and the effect on the respiratory system, gastrointestinal tract, blood and tissues. The section on the clinical administration of cyclopropane is brief and not as complete as a clinician would wish it to be. Complications are dealt

with briefly, as are indications and contraindications. The explosive hazards of cyclopropane are considered briefly. Although common precautions which should be taken when this agent is employed are mentioned, many of the special precautions as they are recognized today are not mentioned. The book is of great interest to the anesthetist because it sets forth the point of view of the pharmacologist and presents data which are not so carefully studied by the clinician as by the laboratory man. The volume is a valuable contribution and should be read by all anesthetists and also those who have to do with the use of cyclopropane as an anesthetic agent.

Dental Caries: Findings and Conclusions on Its Causes and Control Stated in 195 Summaries by Observers and Investigators in Twenty-Five Countries. Compiled for the Research Commission of the American Dental Association by the Advisory Committee on Research in Dental Caries: Daniel F. Lynch, Chairman, Charles F. Kettering, Counselor, William J. Gies, Secretary. Cloth. Price, \$1. Pp. 189. New York, 1939.

This is the compilation of 195 summaries from observers and investigators in twenty-five countries followed by a general analysis, presumably by the secretary of the committee. The material for compilation was obtained by circularization of an "open letter to all investigators throughout the world in the field of dental caries" and directed to "each living person who, from research or clinical observation, has published findings and conclusions that bear in any way, directly or indirectly, on the cause or control of dental caries in man or animals." Further in the preface this statement is made: "It was not our purpose to evaluate the findings and conclusions in this book, nor to suggest which views may be regarded as most significant. Presumably, these functions will be performed publicly by reviewers and special students of caries." In spite of this the general analysis is of no little assistance in bringing order out of what would otherwise be a chaotic situation, and a situation which a reviewer could not at all clear up publicly in the space usually allotted to a review. The book serves one useful purpose; namely, and in the language of the committee, "We aimed only to compile the data and to make them readily available for constructive use by those who will promote public discussion, and who will advance further research and clinical inquiry." And again quoting: "The critical reader will be the judge of the relative values of the individual contributions." There is a definite need for such discrimination.

A Textbook of Psychiatry. By Arthur P. Noyes, M.D., Superintendent, Norristown State Hospital, Norristown, Pennsylvania, and Edith M. Haydon, A.B., R.N., Superintendent of Nurses, St. Elizabeths Hospital, Washington, D. C. Third edition. Fabrikoid. Price, \$2.50. Pp. 315. New York: Macmillan Company, 1940.

In this edition there are additional data on nursing treatment. A psychiatric nurse collaborated with the senior author in the presentation of the latter material. The book is primarily written for the student nurse and as such fills a great need satisfactorily. There are thirty-three chapters, all dealing with some phase of normal and abnormal behavior. Some of the chapters are written too briefly, even though the book is written for nurses. There is a short but good history of psychiatry and of psychiatric nursing. The book is recommended for student nurses and graduate nurses interested in psychiatry.

Feeding the Family. By Mary Swartz Rose, Ph.D., Professor of Nutrition, Teachers College, Columbia University, New York. Fourth edition. Cloth. Price, \$3.75. Pp. 421, with illustrations. New York: Macmillan Company, 1940.

This is one of the most authoritative and reliable books available in the field of nutrition. The numerous editions through which it has passed and its widespread use testify to its value. In her preface, Dr. Rose emphasizes the increased emphasis on the feeding of the child, on the feeding of the mother during the critical antepartum period and the feeding during the first years of life. There is also a discussion of the ideal maintenance diet for the adult. Economic considerations have caused a scrutiny of diets with a view to possible improvement without undue increase in cost. Attention is called also to the new emphasis that has been given to thiamine in recent years. A section on allergy has been added to the chapter on feeding the sick. The book can be unhesitatingly recommended for use as a text, for the physician who needs constantly at hand a reliable work of reference and, indeed, for the general reader.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice: Sponge Left in Abdomen: Res Ipsa Loquitur.—The physician defendant performed a cesarean section on Mrs. Key. As the patient appeared to be "a poor surgical or anaesthetic risk" it was deemed necessary to complete the operation as quickly as possible. While suturing the incision made in the uterus the physician called for a count of the sponges which he had removed from the field of operation. The nurses who were assisting him made the count and told him that it was correct and he then closed the abdominal incision. He again called for a sponge count and was again informed that the second count was correct. All the sponges used to pack off the field of operation were personally placed by the physician and were removed by him. About five weeks later it was discovered that a sponge, which had been used to prevent the transverse colon from sagging into the field of operation, had been left in the patient's abdomen. The patient and her husband subsequently sued the physician for malpractice, alleging that he had been negligent in allowing the sponge to remain in the patient's abdomen. The trial court, apparently relying on the doctrine of *res ipsa loquitur*, found, in effect, that the physician had been negligent and the physician appealed to the district court of appeal, second district, division 2, California.

The defendant contended that there was no evidence adduced at the trial to support the finding that he had been negligent. While he conceded that the doctrine of *res ipsa loquitur* was applicable, he contended that the inference of negligence, which the application of that doctrine would attribute to him, was rebutted by his own uncontradicted testimony that in performing the operation he had followed the usual, ordinary and approved medical practice. He argued that any possible inference of negligence arising from the application of the doctrine of *res ipsa loquitur* was overcome by the facts that (1) there was no medical expert testimony to any other effect than that he had followed approved medical practice in performing the operation and (2) that what is or is not proper medical practice can be established only by medical expert testimony, which, when not conflicting, is conclusive. Hence, he insisted that there was nothing in the record on which the trial court's finding of negligence could be based. The district court of appeal, however, held to the contrary. It relied for its decision on *Alcs v. Ryan*, 8 Cal. (2d) 82, 64 P. (2d) 409, in which the Supreme Court of California said:

... the failure to remove a sponge from the abdomen of a patient is negligence of the ordinary type and that it does not involve knowledge of *matéria medica* or surgery but that it belongs to that class of mental lapses which frequently occur in the usual routine of business and commerce, and in the multitude of commonplace affairs which come within the group of ordinary actionable negligence. . . . General negligence cannot be excused on the ground that others in the same locality practice the same kind of negligence.

The physician's testimony, continued the court, that he followed the usual and ordinary practice in performing the operation does not compel a finding that the inference of negligence arising from the fact that he failed to remove one of the sponges was rebutted. The question whether such inference has been rebutted is ordinarily for the determination of the trial court. The court again adverted to *Alcs v. Ryan*, supra, and noted that it quoted with approval from *Davis v. Kerr*, 239 Pa. 351, 86 A. 1007, 46 L. R. A. (N. S.) 611, as follows:

Here the surgeon had reached the conclusion that he had removed all the sponges—a mistaken conclusion, but verified by the nurses' count. In reaching his conclusion, did he exercise ordinary skill? We see nothing in the evidence to warrant the inference that he did not; but, on the other hand, we find nothing to warrant the inference that he did, which is far more important, since the burden of showing care was upon him. Why was a foreign substance left in the parts, which the operating surgeon should have removed? It was for him to acquit himself of negligence with respect to it. The sponge escaped his observation. Why? Was it so hidden and concealed that reasonable care on his part would not have disclosed it, or were conditions such that, in his professional judgment, further exploration by him for sponges would have endangered the safety of the patient? In a word, did he do all that reasonable care and skill would require? Except as one or the other of these questions

can be answered affirmatively from the evidence, the law will presume to the contrary, and attribute the unfortunate consequences to his contributing negligence.

But, continued the district court of appeal, in the instant case there was no evidence that the physician made any attempt by exploration in the patient's abdominal cavity to verify the sponge count which the nurses had announced as correct, nor was it shown that such exploration, if made, would have endangered the patient's safety. It did not appear that the sponge was so concealed that reasonable care on his part would not have disclosed it. On the contrary, the physician's own testimony lent strength to the inference of negligence arising from the application of the doctrine of *res ipsa loquitur*. His testimony was that the sponge which he had left in the patient's abdominal cavity was of the type used by him in every cesarean operation and was one which he used for the same purpose and placed in the same position in the abdominal cavity. It thus appeared that the sponge in question was of the ordinary type placed as a routine in the same position in every operation, and no compelling explanation was offered for his failure to remove it. The trial court was therefore justified in drawing the inference from the facts proved that the physician did not do all that reasonable care and skill would require.

The physician, continued the court, rested his case entirely on the testimony that in completing the operation as speedily as possible and in relying on the sponge count by the nurses he was following the usual and ordinary practice of other physicians in the same locality. But, a physician cannot relieve himself of liability by proof of a custom or practice among physicians requiring nurses to count the sponges used in an operation. The court concluded that, since the operation in question was performed under his immediate supervision and direction, the defendant physician was charged with the responsibility of determining that all sponges were removed from the field of operation before the incision was closed.

The judgment in favor of the patient and her husband accordingly was affirmed.—*Key et ux. v. Caldwell (Calif.)*, 104 P. (2d) 87.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Pregnandiol Determination as Aid in Clinical Diagnosis.—According to Buxton, the determination of the metabolism and excretion of progesterone, the corpus luteum hormone, has heretofore been impossible because there has been no accurate method for measurement of this substance either in the body or as an excretion product. The discovery of pregnandiol and its identification as an excretion product of progesterone has made it possible to determine the presence of progestational activity with a fair degree of accuracy. The metabolism of progesterone to sodium pregnandiol glucuronide in the body is a complex process. Pregnandiol determinations were done on four women during and following the injection of 30 mg. of progesterone daily for three days. Three of these patients had had a subtotal and one a total hysterectomy. Two of the patients excreted sodium pregnandiol glucuronide, whereas the other two did not. It has been found that men receiving injections of progesterone excrete large amounts of sodium pregnandiol glucuronide. The uterus, therefore, is not considered a necessary adjunct to this metabolic process. Its synthesis as sodium pregnandiol probably occurs in the liver. Since the metabolism of progesterone apparently involves a number of factors, an investigation was made of various laboratory animals. It was found that the urine of monkeys, cats and rabbits does not contain pregnandiol either normally, during pregnancy or after progesterone injections. The greatest yield and purest form of pregnandiol glucuronide occurs in the urine of pregnancy. No pregnant women have been observed who do not excrete pregnandiol glucuronide. Therefore negative diagnosis of pregnancy may be made from a negative pregnandiol determination. Pregnandiol is present in small amounts in the urine of normal women during the latter half of the menstrual cycle. Although

the excretion during pregnancy is greater than that during the luteal phase of the menstrual cycle, a diagnosis of pregnancy cannot be made on this basis because the quantitative determination is not sufficiently accurate. Five cases of habitual abortion were tested for pregnandiol excretion during subsequent pregnancies. One of these patients aborted spontaneously during the course of progesterone therapy. She showed unusually low pregnandiol excretion. Seventy-eight simultaneous pregnandiol determinations and endometrial biopsies were done on patients, most of whom were in the sterility clinic. These tests were done in order to ascertain the accuracy of these two methods of determining progestational activity. It is apparent that pregnandiol is excreted during the time that the endometrium is being activated to a secretory phase and only during that time. There are so many factors controlling the excretion of pregnandiol glucuronide that the quantitative result is liable to variation. Therefore diagnosis cannot be made on a basis of quantitative differences in excretion.

Evaluation of Stilbestrol as Therapeutic Estrogen.—According to Salmon and his associates, numerous clinical reports attested the fact that, in human beings, stilbestrol was capable of relieving menopausal symptoms. The authors studied the biologic and therapeutic effects of stilbestrol in forty-five cases. The investigations included the effect on the vaginal smear, vaginal mucosa and endometrium, the capacity of the substance to inhibit the excessive gonadotropic hormone excretion in the menopausal patient and its effectiveness in relieving the menopausal symptoms. The studies revealed that stilbestrol has an estrogen-like effect on the human vaginal mucous membrane and endometrium; that if sufficient stilbestrol is administered it appears to inhibit the excessive excretion of gonadotropic substance in the menopause. Stilbestrol relieves the hot flushes of the menopause but it does not impart to the patient the feeling of well-being and relief from nervous instability that usually result from treatment with the natural estrogens. Toxic symptoms were observed in 64 per cent of the forty-five patients. The toxic symptoms most commonly noted were nausea, vomiting and vertigo. The authors are of the opinion that the high incidence of toxic symptoms militates against the usefulness of stilbestrol as a therapeutic agent.

Local Use of Sulfanilamide in Trachoma.—According to Cosgrove, 206 cases of trachoma have been diagnosed and treated by clinics held in the northwest and northern parts of Arkansas. The patients (ninety-seven) with no apparent physical disability which would contraindicate oral administration of sulfanilamide were given 20 grains (1.3 Gm.) of the drug daily to an adult male, 15 grains (1 Gm.) to an adult female and 10 grains (0.66 Gm.) to a child. In addition an 0.8 per cent solution of sulfanilamide was given to the patient to be dropped into the eyes from four to six times a day. The patients who were not considered good risks for oral treatment were given only the local treatment. Patients were instructed to cleanse the eyes with warm water every morning and evening. No other medication was used. All the patients reported a cessation of lacrimation and photophobia within the first three days. Sixty-three

patients who received oral medication were reexamined and questioned regarding undesirable symptoms. At least thirteen patients discontinued the oral medication, thus increasing the number of those who in reality received only local treatment. No discomfort was reported by these patients. Improvement in visual acuity among patients given oral and local medication indicates that 46 per cent had a visual acuity of 20/70 or better, and 19 per cent were improved to 20/30 or better. Of the patients who received only local treatment 62 per cent had a visual acuity of better than 20/70 and 31 per cent improved to 20/30 vision or better. The trachoma of the two groups of patients was similar; thus the greater percentage of improvement with local medication was not influenced by the stage of trachoma. It is probable that in a larger number of cases the percentages would have been more nearly equal. Thus the symptomatic relief of the patient with trachoma on local sulfanilamide is apparently as rapid and complete as that obtained from oral medication. The results also reveal that small doses of sulfanilamide supplemented by local application can be used in ambulatory clinics with the same results as are obtained from large doses. The author suggests that it may be possible to prevent the recurrence of trachoma after sulfanilamide therapy by its continued local use with no danger to the patient's health.

Psychoses in Pregnancy and Childbirth.—Smaldon studied the records of 220 women admitted to the New York Hospital, Westchester Division, because of mental illness associated with childbirth and the puerperium. These cases comprised roughly 8 per cent of the female admissions during the period (1922 to 1938) under study. This coincides with certain other published data. Williams has stated that only one in 1,000 women are so affected during pregnancy or childbirth. Manic-depressive psychoses accounted for 107 of the cases, dementia praecox for sixty-four, psychoneurosis for twenty-eight, psychosis with a psychopathic personality for ten, toxic-exhaustive psychosis for eight, a psychopathic personality with pathologic emotionality but without psychosis for two and a paranoid condition for one. Contrary to other reports, only 3.6 per cent of the cases were classified as deliriums directly attributed to the toxic-exhaustive factors of reproduction, although such factors were frequently precipitating causes in the development of rather typical manic-depressive reactions, particularly of the depressive type. Probably this difference in diagnosis may be attributed to the increasing recent tendency away from the belief that a specific psychosis occurs in the pregnant and postpartum states and toward the conception that the physical and psychic problems of childbirth do not determine the type of psychosis but merely act as exciting or precipitating agents. This is particularly attested by the fact that most of the toxic-exhaustive cases

were so diagnosed in the first half of the period under study. Further, a variance of many of the previously reported dynamic factors was found, emphasizing the difficulty of generalization regarding the mechanisms of these reactions. Undoubtedly the psychoanalytic explanations given of certain cases are quite correct but the author wonders whether one can postulate from these cases that other similar cases develop from a similar set of circumstances and by means of the same dynamics. It seems to him that each case of postpartum illness must be considered as an individual, nongeneralizable problem. His study does not corroborate the fact that a high proportion of the depressive type of manic-depressive psychoses and puerperal schizophrenias are of paranoid reaction. It rather shows a greater percentage of catatonia. The study corroborates the observations of Strecker and Ebaugh that these schizophrenic reactions frequently show pronounced manic-depressive symptoms, clouding of the sensorium and a tendency to remissions, that these cases tend to slow deterioration and that a high percentage of postpartum psychoses occur in the Jewish race. The slow deterioration may be due to the predominance of catatonic types rather than to a modification of the schizophrenic process by the reproductive process. The study shows a considerably greater morbidity in the heredity of the manic-depressive group than in the schizophrenic and toxic-exhaustive groups, and a still greater morbidity in the heredity of the psychoneurotic and psychosis with psychopathic personality groups. Many personality deviations were not observed. A high percentage of incest and homosexual ideas, considered by Zilboorg to be typical of puerperal depressive reactions, was not found. Likewise contrary to his claim a slightly greater number showed a mother preference. The study tends to corroborate to some degree Zilboorg's claim that the aloof, shy woman with little previous contact with men and prolonged courtship tends to develop puerperal schizophrenia. Antagonism toward the child, as expected from Zilboorg's hypothesis, was present. With few exceptions the psychoses did have their onset post partum. The schizophrenias reported by Zilboorg developed predominantly in multiparas, while those of the present series were slightly more frequent in primiparas. His assumption of the masculine role in the interval between pregnancies was lacking. A sense of guilt was found more frequently than by Zilboorg.

Hookworm in Southern States.—Keller and his associates present data on the incidence of hookworm in the Southern states in which a plan of control was instituted by the Rockefeller Sanitary Commission in cooperation with the state departments of health. Hookworm surveys were made in eight Southern states during the periods 1910-1914 and 1930-1938. In the early period 577,590 specimens of feces were examined, and in the later period 424,511. The numbers found positive in the early and later periods were 240,895 and 81,913 respectively. After adjustment for the distribution of the population the percentage found positive in six of the eight states was 36.6 in the earlier period and 11.2 in the later period, resulting in a reduction of 68.3 per cent. In the later study the states in the order

of prevalence from highest to lowest were Mississippi, South Carolina, Alabama, North Carolina, Kentucky and Tennessee. While there is a widespread distribution of hookworm, the areas of highest incidence are confined to the coastal plain and sandy soil areas of each state. The age distribution shows that the greatest prevalence was in the group 5 to 19 years of age. The peak of incidence, 24.5 per cent, was reached in the age period 15 to 19. In preschool children and adults the incidence was about half as great as that found in the school age group. The distribution of all positive cases shows that about one fourth of the individuals had moderate, heavy or very heavy worm infestations sufficiently severe to produce clinical symptoms. The remainder of the cases were classified as very light or light infestations. The data analyzed with reference to household groups seemed to indicate that the individual worm burden tended to increase as the number of infested persons in the family increased. A comparison was made of hookworm in 17,458 Negroes and 59,028 white persons in the same counties during 1930-1938. The incidence in Negroes was about one fourth that in white individuals and the average intensity of infestation was about one half that found in white persons.

Indications for Lobectomy and Pneumonectomy for Tuberculosis.—Samson discusses indications and contraindications to lobectomy and pneumonectomy in tuberculosis and reports three instances of each. The appreciation of tuberculous bronchial stenosis with its resultant pulmonary atelectasis has followed the increasing use of the bronchoscope in cases of pulmonary tuberculosis. This type of case, which is not uncommon, refutes the belief that pulmonary atelectasis is a favorable prognostic sign in tuberculosis. Most of these patients cannot become entirely and permanently well without surgery. Indications for lobectomy differ from those for pneumonectomy. Stenosis of the lobar bronchus was not a factor in the three cases of lobectomy. The position of the cavity was important. Their presence in the lower and middle lobes indicated lobectomy and made the effectiveness of thoracoplasty doubtful. Pulmonary resection carries a greater risk than thoracoplasty. In cases in which thoracoplasty is not suitable and in those in which it has been performed without cure lobectomy may be indicated. The tuberculosis should be sharply limited to the portion of the lung to be resected. Lobectomy and pneumonectomy may be primary or secondary procedures. In the latter are those cases of pulmonary resection designed to remove cavity-bearing pulmonary tissue which has not been collapsed by a technically adequate thoracoplasty. The advisability of removing a lobe in which a cavity has not been collapsed by a pneumothorax is probably unwise without first obliterating the interpleural space by thoracoplasty. Planned pulmonary resection, not preceded by thora-

coplasty, may be listed as a primary procedure. Pneumonectomy should be considered for patients with total atelectasis of one lung and advanced fibrous stenosis of the stem bronchus who occasionally suffer from obstructive symptoms not relieved by bouginage of the stricture. Pneumonectomy probably should be deferred until mucosal healing and fibrostenosis have occurred in cases in which bronchial obstruction is due primarily to extensive ulcerative disease. A large isolated cavity in a lower or middle lobe is the first indication for primary lobectomy. The decision is strengthened by the presence of concomitant atelectasis and bronchiectasis or by a stenotic lobar bronchus. Obviously pneumothorax, phrenic paralysis and pneumoperitoneum, or a combination of these procedures, will have been tried prior to considering lobectomy. Repeated severe hemorrhages from a tuberculous cavity is a further indication.

Tuberculosis of Stomach.—According to Sullivan and his associates, from 1929 to 1938 in 11,480 consecutive necropsies performed at the Cook County Hospital there were 288 cases of pulmonary tuberculosis and in 242 additional cases pulmonary tuberculosis was found incidentally, death occurring from some other unrelated cause. There was one instance of tuberculosis of the stomach encountered in the former group of cases. In a third group of twenty-four cases in which a generalized tuberculous adenopathy was the primary cause of death, one case of tuberculosis of the stomach was present. Thus in 554 cases of tuberculosis the stomach was involved in two cases, while during the same time only one case was encountered in 75,000 surgical specimens. Pathologically, two types of tuberculosis of the stomach are to be discerned: 1. Miliary tuberculosis, in which the stomach contains single caseous tubercles which are located in the submucosa or on the serosa and are a part of the stage of generalization. 2. Ulcerative tuberculosis, which is characterized by numerous shallow, irregularly shaped ulcers with overhanging margins and grayish yellow bases, which rarely penetrate the muscular layer. They may eventually cause scarring and shrinking of the stomach, simulating syphilis or carcinoma. The sources of infection are thought to be direct invasion of the mucosa through the blood stream or lymph or by direct extension. Two of the cases were of the ulcerative type. The case of a 34 year old Negro with tuberculosis localized to the stomach and perigastric lymph nodes is described. Gastric resection has thus far completely eradicated the disease. Epithelioid cell tubercles were present in the gastric wall and in the perigastric lymph nodes. This type of case is of interest to the gastroenterologist and the surgeon in view of the diagnostic problem that it presents. The differential diagnosis usually considered is carcinoma or syphilis of the stomach, and tuberculosis is practically never included. Even the gross examination of the excised segment of the stomach resembles a malignant condition. The correct diagnosis is not suspected until microscopic examination is made. The prognosis is usually good following surgery in cases in which the general condition is fairly good and when there are no signs of active tuberculosis elsewhere in the body. The earliest symptoms are not characteristic. They are usually those of chronic gastritis with loss of appetite and a sense of fullness or pressure in the epigastrium. This is followed by epigastric distress or pain of the ulcer type, loss of weight and vomiting. The vomiting occurs late in the disease and the vomitus is dark or suggestive of gastric hemorrhage.

Obstetric Complications.—Martin studied the obstetric complications which occurred in 4,928 deliveries between 1916 and 1926 and the 5,780 encountered between 1927 and 1937. Pelvic contraction was found in only 187 cases, or 1.75 per cent of the total series. The problem of difficult labor is summarized as follows: The choice of a method of delivery for any given case is never complete without considering the pelvis, position, size of the baby, character of the pains and condition of the soft tissues. The risk to the mother and the child is significantly increased when one factor is unfavorable but is greatly increased when two or more factors are unfavorable. The incidence of cesarean operations in the 1927 to 1937 series of cases has doubled, yet there has been but one death in 278 cases, or 0.36 per cent. The aim is to deliver by low cesarean section women on whom high forceps was used formerly. Low or perineal forceps were used in 8.7 per cent of the total material. No insignificant increase in morbidity, mortality or fetal mortality was associated with this procedure. Mid forceps is limited to compelling indications, usually maternal. High forceps performed in the first series was attended with a 7.4 maternal and a 38 per cent fetal mortality. The incidence of mid forceps has changed but little and still is attended with a high fetal mortality. Delivery by version and extraction has been used in only thirty-eight of the 10,708 cases, and then only when indications for immediate delivery were compelling. Two maternal deaths followed, both in relatively desperate cases. An incidence of 3.48 per cent, or 368 breech deliveries, was conducted without maternal mortality but with an uncorrected gross fetal mortality of 12.3 per cent. All antenatal fetal deaths, macerated fetuses and neonatal deaths due to prematurity were included in this percentage. Toxemia of pregnancy developed in 481, or 4.5 per cent, of the total patients; a hypertension of more than 150/100, along with varying degrees of albuminuria and edema, was present. There were thirty-three other cases of convulsive toxemia or eclampsia. There were four maternal and thirty-seven fetal deaths among the 481 nonconvulsive toxemias. There were no maternal deaths and five fetal deaths among the eclamptic patients. All the fetal deaths were of premature infants. One hundred and twenty-two patients of the total series had complicating organic heart disease and were allowed to reach the stage of viability. There were six maternal deaths, or 4.9 per cent mortality. Twenty-four other women were considered too poor risks from the cardiac standpoint and their pregnancies were terminated by therapeutic abortion. Sixteen of the 122 became decompensated during late pregnancy and

the six maternal deaths occurred among the decompensated cases. Since 1928 such patients have been followed both by a cardiologist and by an obstetrician and the mortality rate has been strikingly reduced; but one death has occurred since 1928. Pregnancy was complicated by diabetes mellitus in twenty-one cases. One maternal death occurred in the preinsulin days, a patient with severe diabetes who died undelivered of a premature infant while in diabetic coma. There were four fetal deaths. Fibroids have not been a particularly serious complication, as there were few cases with large fibroids. An estimated postpartum blood loss of 600 or more cubic centimeters has been recorded in 230 cases. Ninety-eight of the hemorrhages followed an operative delivery. The exact cause of antenatal bleeding was difficult to determine. However, in sixty-seven cases it was of significant amount and was definitely due to premature separation of a normally implanted placenta and in forty it was due to placenta praevia. Among these 107 cases, twenty cesarean sections were performed. In recent years no manipulations or vaginal examinations were carried out in such cases until cross-matched donors were available and preparations for immediate laparotomy were complete. Probably as a result of such precaution and other improvements in postoperative care there has been but one maternal death in the 1927 to 1937 series. There were six deaths during the 1916 to 1926 series. The author points out that conservatism in obstetric management remains the policy of choice, as is evidenced by the 0.21 per cent uncorrected maternal mortality and the 3.6 per cent uncorrected and 1.8 per cent corrected fetal mortality obtained in the 5,780 deliveries seen between 1927 and 1937.

Pfeiffer's Crystallization Method for Diagnosis of Cancer.—Gruner points out that the patterns which crystals assume after the addition of blood to a solution of cupric chloride have been claimed by E. Pfeiffer to be distinctive between health and disease. The pattern characteristic for cancer has been defined by Pfeiffer as built up on a straight line to the center of which impinge a few lines at angles varying from 5 to 30 degrees. Lines at similar angles may meet at the same point from the opposite side of the base line. The two groups of lines together give an appearance recalling that of tyrosine crystals seen under the microscope. The more numerous and the better defined the groupings in a plate, the more advanced is the case considered to be. The fact that cancerous blood really produces differences which are uniform in kind is readily established even with a few dozen tests. The author performed the crystallization on 122 patients in whom the existence of cancer had been proved, on twenty

cancer patients who had been treated, on thirty-three patients without cancer and on a considerable number of normal and tumor-bearing animals. In Pfeiffer's technic one drop of blood is allowed to fall directly from a finger prick into 1 cc. of distilled water. After thirty minutes two drops (0.1 cc.) of this are introduced into 10 cc. of a 20 per cent cupric chloride. After one-half minute the mixture is poured out on specially prepared plates resting in a specially constructed chamber, and the readings are made after eighteen hours. The only innovation which Gruner has made has been the use of polarized light for reading the slides. The results of the crystallizations done with material obtained from the Royal Victoria Hospital in Montreal are recorded in tables which reveal that the crystallization method gave positive results in 110 of the 122 proved cancer patients; the readings were correct in 90.1 per cent of the cancer cases. In the thirty-three patients without cancer, one positive result was obtained; the percentage of correctness was 96.9 per cent. A positive crystallization test may become negative after excision of the cancer or after treatment by radium. Of the twenty treated cases tested by the author, eleven (55 per cent) were negative. Of animals, those which showed spontaneous tumors or had received grafts showed a positive picture in 79 per cent. Eighteen of twenty-two animals in which the graft did not take gave a negative picture. Eight normal animals of forty-five gave a positive picture and these were mice belonging to a cancer-susceptible strain. A positive crystallization need not necessarily be dismissed as wrong, because the clinician cannot find the tumor. On the contrary, if the test is repeatedly positive the patient should be watched carefully.

Tests for Hepatic Damage.—Wilson found that in forty-one patients without obstructive jaundice or biliary fistulas the quantitative level of the plasma prothrombin correlated closely with the quantity of hippuric acid excreted. In addition to normal individuals the study included persons with cirrhosis of the liver, Banti's syndrome, familial hemolytic icterus, pernicious anemia, aplastic anemia, multiple myeloma, polycythemia vera, Hodgkin's disease and leukemia of all types with various degrees of hepatic infiltration. Among those individuals with proved hepatic damage in which the hippuric acid excretion was between 0.86 and 2 Gm. the prothrombin was found to be between 19 and 37 per cent of normal; with from 2 to 3.9 Gm. of hippuric acid excretion the prothrombin level was between 33 and 90 per cent of normal, and with from 3.9 to 4.56 Gm. of hippuric acid excretion the prothrombin level was between 70 and 100 per cent of normal. No consistent correlation was noticed between plasma prothrombin and plasma fibrinogen, particularly when an infectious process was present. The galactose tolerance test was within normal limits in all patients studied. There was a wide variation in the results recorded for the bromsulphalein dye test. There was a definite correlation between the level of the plasma prothrombin and the synthesis and excretion of hippuric acid following the ingestion of sodium benzoate as measured by the method of Quick. Confirmation at operation and necropsy has shown that these two tests are sensitive reflectors of hepatic damage. A relatively extensive degree of damage to the parenchymatous tissue of the liver must be present before it is reflected in many of the commonly used hepatic function tests. The ability of the liver to form prothrombin from vitamin K and to synthesize hippuric acid from sodium benzoate is a more sensitive measure of the amount of hepatic damage present than the majority of hepatic function tests would indicate. Prothrombin cannot be replaced by blood transfusion in sufficient quantity to be of any therapeutic value.

Appendicitis with Complete Situs Inversus Viscerum.—Lawrence cites a case of appendix located on the left side with complete transposition of the thoracic and abdominal viscera, diagnosed by physical examination and confirmed by x-ray study, the electrocardiograph and at operation. This anomaly was first recorded in the seventeenth century, four cases being reported. Many cases are probably not diagnosed, as it is said to occur once in every 5,000 necropsies. Up to 1924, 270 cases had been reported. The anomaly occurs more often in males than in females. In many instances there is a dextrocardia while the other viscera are in their normal position. A complete situs inversus of the viscera is compatible with health and longevity

and except as an anatomic curiosity is important only to the embryologist, cardiologist and surgeon. However, a partial transposition is often troublesome as it may interfere with the function of some parts due to malposition in relation to other organs. A clinical picture of an abdominal lesion except as to location of pain and point of sensitivity should be a warning and the diagnosis should be cleared up by a fluoroscopic examination of the chest, a barium sulfate meal and an enema. The subject is of much importance in abdominal surgery for, as Pol pointed out, more than half of forty-six patients with left side appendix complained of pain in the right lower abdomen, referred pain. Usually pain produced by an irritated abdominal viscus is first referred to the epigastrium and later to the viscus involved or to the opposite side from the viscus involved. The electrocardiograph will clear up the diagnosis of a case of dextrocardia, as lead 1 will be inverted and leads 2 and 3 will be transposed. X-ray study is necessary in diagnosing transposition of the abdominal viscera. The author's patient was a girl of 19 who had been complaining of pain in the right lower part of the abdomen for twelve hours. She had a similar attack one year previously. The maximal cardiac impulse was found in the fifth intercostal space in the right side of the chest. There was rigidity in both the right and the left iliac fossa, but the patient insisted that the pain was mostly in the right side except on deep pressure, when it was more intense on the left. At operation a right rectus incision was made and the sigmoid was found in the right iliac fossa and the cecum in the left fossa. The appendix was delivered without much difficulty, the abdomen was closed and recovery was uneventful.

Nutritional Disturbances and Cutaneous Diseases.—In addition to well recognized deficiency syndromes there are, according to Andrews, a variety of abnormal conditions of the skin and mucous membranes in which the vitamin B complex is an important factor. The action of nicotinic acid and riboflavin on oral lesions is sufficient to suggest its use more widely and perhaps as a routine prior to operation in cases in which other oral lesions are associated with carcinoma of the tongue or buccal cavity. Whereas the results of treatment are not absolutely conclusive there is a strong suggestion that certain cases of oral leukoplakia are manifestations of a deficiency of some fraction of the vitamin B complex. Also some cases of neurodermatitis may have a nutritional background, and photosensitization may in some cases be a manifestation of vitamin deficiency. There are thirty-six (Spies) known dietary constituents essential to adequate nutrition. Little is understood concerning the body's requirements for some of these factors, and even less is known of the interrelationship of these substances to metabolism. The diet is influenced by the age, race, habits, taste and economic status of the patient. In general, however, treatment of deficiency states should include a diversified diet of from 4,000 to 4,500 calories, be rich in meat, liver, eggs and milk, and be supplemented by dry brewers' yeast and some of the fish oils.

Appendicitis with Complications.—Ward points out that the reduction in mortality following continuous gastrointestinal decompression was not great but that it indicated ways of still further improving the results. At the University of California Hospital 206 patients with acute appendicitis were operated on from 1913 to 1925 and 561 from 1925 to 1939. During the latter period decompression was known, but unfortunately not always used. The reduction in mortality was from 5.8 to 3 per cent and an analysis of the causes of death suggests that transduodenal decompression was the most important factor in this reduction. In a group of seventy-two patients with gangrenous, not perforated, appendixes there were no deaths. In the cases in which perforation with local peritonitis had taken place the mortality was reduced from 14.3 per cent in the early period to 5 per cent in the later period. In perforation with diffuse peritonitis the mortality decreased from 40 per cent in the early period to 27.2 per cent in the later period. In cases of abscess in which drainage only was carried out there has been no change in the mortality rate, while for those in whom abscess was treated by drainage and appendectomy the mortality rate doubled. However, two of these deaths were probably unpreventable under any plan of treatment and if they are eliminated the mortality rate would be identical for the two periods. In 41 per cent of the deaths there was a history of the use of cathartics and more than half of the patients had been sick longer than four days before being sent to the hospital. The author believes that only five of the twenty-nine deaths could not have been prevented by any plan of management and that some change in handling might have eliminated twenty-four deaths. The plan of management that he suggests is as follows: 1. Operation for appendicitis should be performed when the diagnosis is made or strongly suspected, except in the presence of diffuse peritonitis, if rigidity has given way to flaccid distention or if the patient is moribund. Such patients are to be treated with immediate intestinal decompression by nasal tube, restoration of fluid and electrolytic balance, use of the Fowler position and morphine. 2. Under spinal anesthesia, or occasionally local anesthesia, reinforced by pentothal sodium or evipal soluble administered intravenously, the appendix should be approached through a gridiron incision over its suspected site and removed with the cautery under adequate exposure with continuous suction evacuation of pus or serous fluid and with a minimal disturbance of the surrounding structures. The stump should be closed by simple ligation or inversion without ligation if the cecal wall is not indurated and the abdominal cavity without drainage, unless a well walled-off abscess has been found. 3. The abdominal wall should be drained adequately in the infected cases or the wound packed with petrolatum gauze if greatly contaminated. 4. Post-operatively, intestinal decompression should be instituted without waiting for distention. Comfort and intestinal tone should be maintained by morphine, fluid and electrolytic balance according to the plan laid down by Collier, and fluids and food by mouth should be withheld until peristalsis has returned without the use of artificial stimulants. 5. An aerobic and anaerobic culture should be obtained at the time of operation for guidance in

specific postoperative therapy. As a test of the plan the author says that in his last hundred personal cases in which he followed these rules there have been two deaths. Both patients were inmates of a home for the aged and their necropsy reports read like a catalogue of diseases of mankind and included everything from syphilis to coronary occlusion. Both had a gangrenous perforated appendix and he thinks that death was inevitable.

Prostigmine for Ureteral Stones.—Scholl suggests that one or two series of injections of prostigmine methylsulfate be given every patient with ureteral stones before any manipulative or surgical measures are instituted. He used the drug in fifteen personally observed cases, and in seven it was of definite help. In all except three cases, in which small stones were present in the lower ureter, some other procedure was also used; usually the passage of a soft ureteral catheter up to or by the stone in an effort to establish the diagnosis. In none of the fifteen cases were stone dislodgers, metal dilators or multiple catheters used. In the three cases with small stones, the stones were passed promptly after the first prostigmine injections. Hager's original recommendation of dosage is still the most satisfactory.

Thyroid Surgery in Cardiac Disease.—Pemberton and Miller believe that for a complete conception of cardiac physiology in relation to the hyperthyroid states the condition must be thought of in terms of altered, increased metabolism. A certain degree of cardiovascular disturbance is almost invariably associated with thyrotoxicosis. Thus in such cases the clinical signs related to the cardiovascular system are easily explicable on the basis of an increased circulatory rate. The latter is merely the result of the changes in the body economy dictated by an increased metabolic rate. The most common disorder of cardiac rhythm is auricular fibrillation. Its persistence following thyroidectomy is suggestive of the presence of associated primary cardiac disease, residual cardiac injury from protracted hyperthyroidism or recurrent hyperthyroidism of exophthalmic goiter. Most of these patients are prepared for operation in about two weeks and are not hospitalized unless congestive failure is present. Patients suffering from congestive heart failure should have rest and be treated for primary cardiac disease without hyperthyroidism. When compensation is attained the patient should be ambulatory in a limited fashion for several days. Debilitation from prolonged rest and the ravages of hyperthyroidism make him susceptible to postoperative pulmonary complications. This period of limited activity also affords a test of cardiac reserve. The most frequent accompanying cardiac disorders are coronary sclerosis and coronary and hypertensive cardiac disease. Cardiac disease as a complication accounts for approximately 81 per cent of the total mortality. However, even though the chances of recovery are slim the surgeon must remember that his estimate of risk is subject to error and that every patient should be given the opportunity to avoid the status of a "cardiac cripple." An analysis of the causes of death reveals that the primary cause was bronchopneumonia. This proves the value of establishing precautionary measures in the entire period of treatment to avoid respiratory infections. Attention should also be focused on atrophy of the liver. The relation of hepatic failure to surgical risk in cases of hyperthyroidism has not received sufficient consideration. Because of the high risk entailed, every possible precaution must be exercised and technical errors avoided in these cases. The choice of the anesthetic agent to be used is a prime consideration. Local infiltration supplemented by inhalation of nitrous oxide and oxygen has proved effective. Prolonged anesthesia by inhalation is avoided and the susceptibility to pulmonary complications is reduced. The average duration of inhalation anesthesia will be from eight to ten minutes. Local anesthesia, unsupplemented, is indicated for patients with obstructive dyspnea. The indications for lobectomy are limited. Patients in an extremely toxic condition with limited reserve and patients with congestive heart failure may have to be subjected to lobectomy to minimize the hazard. Such patients need special preoperative and postoperative preparation. Such care is most effectively achieved by the internist and the surgeon as a team. The risk of operation for such individuals is great but when the great number of excellent results are reviewed it seems justified.

Corneal Inflammation in Chickenpox.—Loewenstein reports two cases of iris disorder following chickenpox which is parallel to that seen in smallpox, in herpes iridis (herpes zoster), in inoculated herpes iridis in rabbits and in vaccinia. Depigmented spots of the iris remained after the exanthem healed. This, the author says, completes his earlier observation of vitiligo iridis following chickenpox. He believes that the now recognized forms of vitiligo iridis in smallpox, chickenpox, herpes iridis (zoster), inoculation iritis in rabbits (herpes febrilis) and scarlet fever present a unity from which a biologic relationship between their germs can be deduced. The corneal infection does not correspond with any known change of the cornea. It cannot be confused with anything else. The involvement of the deeper layers of the corneal parenchyma in the first weeks of the infection and their rising to the surface later on is striking. The concomitant iritis is a slight one. The slit lamp depicts only the tiny exudate on the lens capsule. No opacities in the fluid of the anterior chamber are detected and no new formation of vessels in the cornea. Photophobia is absent even toward the end of the inflammation when the surface layers (epithelium) are more involved. The author thinks that this observation is the long sought "missing link." On biologic grounds, being aware of the appearance of a vitiligo iridis in chickenpox, one expected to find the process causing the acute disease—a process which had previously escaped observation. As the assumed virus of chickenpox is related to the virus of herpes, it was to be expected that the clinical picture of chickenpox keratitis would be very similar to that of a deep herpes. This assumption proved to be true. He wonders how the disturbance escaped recognition with chickenpox being so widespread. He does not believe that the corneal involvement in chickenpox is a rare one, but since the majority of chickenpox cases heal without medical assistance and parents know that even the eye complications are not dangerous, ophthalmologists do not attend the patients and therefore the condition has apparently been missed.

Pulmonary Embolism and Infarction.—According to Parsons-Smith, pulmonary embolism is a disability chiefly affecting people at or past middle life. A variety of factors are concerned in the formation of the thrombus from which the embolus originates. They include local trauma, the presence of organisms and several morbid developments such as slowing of the blood stream, chemical and physical changes in the blood and injury of the vascular epithelium. The primary thrombosis occurs often in the external iliac, the femoral or the saphenous veins; but other vessels—the inferior vena cava and the pulmonary and internal iliac veins—may be responsible, as also may the heart itself in the advanced stages of myocardial failure. The clinical picture of embolic obstruction of the main pulmonary artery or its major branches is moderately distinctive. Some of these cases are immediately fatal; in others characteristic signs and symptoms are observed for varying periods before death, the patient being suddenly seized with breathlessness, faintness and feelings of severe substernal oppression which tend to persist in spite of treatment. Physical examination discloses the shock syndrome. Characteristic signs include pallor, sweating, lividity and dilated pupils; the pulse is rapid and soft and the blood pressure considerably lowered; the respiratory rate is accelerated and its excursion usually diminished; collapse, often ushered in by uncontrollable vomiting, deepens, and unconsciousness generally preludes death. It may prove difficult to differentiate pulmonary embolism from coronary thrombosis, because during the early stages the two are singularly alike. The clinical phenomena common to both are pain in the chest, tachycardia, rapid respiration, pallor, cyanosis and a soft and frequently imperceptible pulse, a falling blood pressure, shock with syncope tendencies, sweating, vomiting and cardiographic signs typical of myocardial ischemia. The past history of the patient and the circumstances leading up to the onset of the illness will often furnish details helpful in the differential diagnosis. Previous heart disease, an exhausting period of decompensation and the clinical phenomena suggestive of long-standing hypertension or a history of effort angina favor the development of coronary thrombosis. On the other hand, pulmonary embolism might be suspected if the acute seizure is a sequel to an operation or accident. Moreover, the pain of pulmonary embolism is usually referred to the side of the chest rather than to the substernal region. Other features peculiar to pulmonary embolism include extreme cyanosis and breathlessness associated with shallow respiration, the discomfort in the side being intensified by any attempt to increase the depth of the breathing. Apart from cases of massive embolization in which pulmonary edema occurs rather than hemorrhagic consolidation, the incidence of true infarction with moderate-sized emboli is relatively small. Chronic cardiac disease, postoperative invalidism and septic wounds seem to favor the formation of pulmonary infarcts, the responsible factor being passive hyperemia in the lungs. A slightly raised temperature and a relatively rapid pulse may be the only indications that a focus of phlebitis and venous thrombosis which may be responsible in due course for embolization in the pulmonary circuit and, later, for a hemorrhagic infarct, is in process of formation. As early indications of the latter, the temperature and the pulse rate rise abruptly, the respiration quickens, and the symptoms of shock and mental anxiety are intensified. Pain, exaggerated by deep breathing, is another early symptom. The physical signs of pulmonary infarction are rarely distinctive. A friction rub may be audible; there may be a circumscribed area of dullness with rales and altered breath sounds and diminished expansion on the side of the lesion. X-ray examination is often a valuable aid in the diagnosis. The clinical picture of pulmonary embolism and infarction should be supplemented by electrocardiographic investigation.

Capillary Fragility.—Bell and his colleagues sought to determine the variations in the capillary fragility by Göthlin's test among 346 healthy British students, to define the range of normality and to determine the effect of ingested vitamin C on those students considered to have an increased capillary fragility. The number of small cutaneous hemorrhages occurring under standard conditions was taken as an index of the capillary fragility or resistance. Variations in the illumination altered the mean number of petechiae detected. A 300 watt lamp at a distance of 2 feet proved to be a good illuminating standard. Among 89.3 per cent of the students, less than eight petechiae were found. Under the conditions of the test eight or more petechiae may be regarded as unusual; this agrees with the opinion reached by Göthlin. The ingestion of vitamin C by the thirty-five students who had a petechial count of eight or more reduced the petechial count to less than eight in two weeks. The ingestion of vitamin C had no effect on petechial counts of less than eight. The antecubital fossa was found to be as suitable as the forearm for the test. There were five healthy persons among the 346 whose increased capillary fragility was not influenced by the administration of vitamin C or of vitamin P. This, the authors believe, is the only reported group of healthy people with an increased capillary fragility resistant to treatment with vitamin C in whom the effect of vitamin P has been studied. Apart from abnormal influences—for example fever and the administration of heavy metals—two factors influence capillary fragility in health: menstruation and ascorbic acid. Other factors may be involved, as in the few students whose high petechial counts were unaffected by the administration of vitamin C or any other factor so far known. The authors found that even when the conditions were carefully standardized it still remained difficult to assess the capillary fragility of the subject. Variation in the values found on the right and left arms of a single individual were frequent. Therefore they suggest that the average of the petechial count on the two arms of an individual appears to give a more accurate indication of the true capillary fragility. Göthlin now makes all determinations on both arms and proceeds from the mean figure of the two determinations.

Excretion of Pregnanediol in Toxemia of Pregnancy.—Cope states that observations on ten pregnant women suffering from toxemia uncomplicated by nephritis have not confirmed the claim that the amount of the sterol complex pregnanediol glucuronide excretion, which is abundant in the urine in normal pregnancy, is greatly reduced in late toxemia of pregnancy. Pregnanediol was, however, absent in the last week of pregnancy from the urine of a pregnant woman with chronic nephritis. This suggests to the author that renal damage may be a more likely cause of interference with the excretion of pregnanediol. He considers it unwise to conclude that any difference which may be found between the rates of excretion of pregnanediol in normal pregnancies and in pregnancy toxemia is necessarily due to the toxemia, for the excretion of pregnanediol might be interfered with by many conditions of ill health other than toxemia. He has compared the daily excretion of pregnanediol glucuronide in late pregnancy toxemia with that of women having other general diseases late in pregnancy. The patients with pregnancy toxemia not only had a persistent albuminuria but also a raised blood pressure with or without edema, and one woman had severe eclamptic fits. The study shows that in none of these cases was the daily excretion low (from 28.5 to 55.8 mg.); the mean daily excretion was 39.4 mg. The excretion among the ten pregnant women with other diseases

(hypochromic anemia, cardiac failure, diabetes mellitus, pyelitis and others) were much more variable; the mean value, 49.5 mg. a day, was essentially the same as in normal pregnancies. It was rather higher than the mean of the toxemic group, but the difference does not seem large enough to be of significance.

*War Injuries of the Thorax. T. Naegeli.—p. 674.
*Diseases of Coronary Vessels and Military Service. M. Holzmänn.—p. 676.

War Injuries of the Thorax.—Naegeli points out that the prognosis in cases of bilateral pneumothorax is grave. In unilateral open thoracic wounds a displacement of the mediastinum toward the uninjured side occurs with decreased ventilation of the uninjured lung and unsatisfactory blood arterialization as a consequence. In gaping intercostal soft part wounds the collapsed lung may eventually be pressed out of the thoracic wound by means of compressed breathing enabling thus the wound to close, or else the retracted lung may be fixed by lying on the wounded side or by percutaneous suture. Even closing of the thoracic wound with airtight dressing or suturing soft parts improves the patient's condition, as the injurious variations in pressure during breathing become thereby eliminated. The consequences of valvular and tension pneumothorax are tympanites over the lungs, widening of the intercostal spaces, cyanosis and dyspnea. It is treated by puncture, preferably with a cannula provided with a valve toward the outside. Severe phenomena of displacement due to hemorrhage following injury of a lung vessel also require puncture. A small blood transfusion favors arrest of the hemorrhage. The mediastinal emphysema requires an incision into the suprasternal fossa. In pleural empyemas, puncturing and suction should be used. Change of dressing should possibly be done without getting air into it. In view of possible infection, large and particularly torn soft wounds of the thoracic wall should be excised and eventually sutured. Morphine should be amply administered during the first days. The patients may be best transported in a sitting position leaning on the injured side. Severely wounded patients or patients who have been operated on should not be transported for twenty days at least.

Coronary Vessel Disease and Military Service.—Holzmänn states that in diseases of the coronary vessels the main clinical symptom is angina pectoris. Three types may be distinguished: 1. The effort-angina of fifteen minutes duration at the most, caused by a transient and reversible coronary insufficiency. 2. Increased attacks of angina that may occur at rest and may last longer than fifteen minutes, caused by increased and protracted coronary insufficiency. They are reversible, although they leave behind a lasting ischemic injury to the myocardium. 3. The status anginosus of greatest intensity, caused by an acute irreversible coronary occlusion with a massive infarction of the heart as a consequence. It often occurs without provocation and lasts from hours to days. Gradually

and imperceptibly developing coronary stenosis is at the bottom of the first two forms. Thrombotic occlusion of the small coronary arterial branches may occur in the second form. An acute thrombosis of an important coronary arterial branch occurs in the third form. Besides the degree of impassibility of the diseased vessels, the ability of accommodation of the collateral circulation is significant. Anginal pains are not necessarily caused by disease of the coronary vessels. They may also be produced by a transient functional disturbance, as in case of angina pectoris vasomotoria or in the initial stages of tobacco angina. They may be the consequence of a relative coronary insufficiency, as in case of hypertrophic hearts. The angina pectoris ambulatoria is typically localized, radiating into the left shoulder, left arm or both arms. It lasts a few minutes and is influenced by physical effort, whence the diagnostic value of carefully dosed physical labor. A glyceryl trinitrate tablet dissolved in the mouth may also demonstrate the ischemic nature of the ailment by its quick sedative effect. In status anginosus of greatest intensity the pain can be allayed only with morphine or its substitutes. In the presence of a coronary circulatory disturbance the army physician should hospitalize the patient for further examination. This consists in taking electrocardiograms at rest and in case of negative observations after physical labor. Fluoroscopy of the thorax, blood pressure, sedimentation and Wassermann reactions complete the examination. Should this disclose a lesion of the myocardium or a coronary insufficiency, the patient should be kept under observation and treatment until the symptoms have disappeared or a stationary condition has been obtained. The following situations may arise before the military examining commission: 1. No more anginous symptoms, heart physically normal, electrocardiogram normal, no heart insufficiency: dispensation from service for three months. In case the physical condition remained satisfactory after a trial period in service following the dispensation period: fit for auxiliary service, armed eventually. 2. Anginous symptoms still present or electrocardiogram shows pathologic condition, eventually both, physically unnoticeable or slightly abnormal heart condition, no heart insufficiency: administrative auxiliary service at most. 3. Presence of heart insufficiency, electrocardiogram reveals pathologic condition, whether angina pectoris is present or not and whether physical heart condition is abnormal or not: unfit for service. Estimation of military insurance liability remains subjective. Refusal of claim is justified only when symptoms occurred without strenuous physical labor and infectious or toxic influences in service, provided prompt medical measures were taken. The safest estimate can be made in case of death and necropsy.

*Sulfanilamide in Treatment of Erysipelas in Children. F. Bazán and R. Maggi.—p. 593.

Sulfanilamide in Erysipelas in Children.—Bazán and Maggi used sulfanilamide in the treatment of acute erysipelas of the head and face or the limbs of thirty children ranging in age from 2 to 10 years. The disease developed in the majority of cases in the course of convalescence from scarlet fever, diphtheria or chickenpox. The drug was given by mouth in daily doses which varied between 0.1 and 0.15 Gm. for each kilogram of body weight, in three or four fractional doses, up to forty-eight hours after the return of the temperature to normal, after which half the dose was given for two or three more days. The treatment as a rule lasted from five to eight days. All the patients recovered. Improvement was noted on the first day of treatment by the arrest of the spread of the lesion and a diminution of inflammation, redness and local tension. The authors found that the height of fever and the course of the disease were favorably influenced by sulfanilamide and that the duration of both diminished when compared with the effects of previous therapeutic methods. They conclude that sulfanilamide is the treatment of choice in erysipelas of children, since the treatment is well tolerated and yields a recovery in 100 per cent of the cases. The drug appears to have a specific effect on the streptococcus and on the disease itself.

Alimentary Chloridemia in Diseases of the Liver. L. S. Litshits and E. V. Kosevich.—p. 185.

Treatment of Parenchymatous Jaundice.—In his clinical observations on thirty-six cases of jaundice, Firdman noted a positive urobilin reaction in the course of the disease indicating the presence of a hepatitis. Fractions of bile from the duodenal contents revealed cloudiness in fractions A and C, leukocytes, cylindric epithelium and mucus on microscopic examination. Toward the termination of the disease the duodenal bile became clear and transparent. The patients were treated by intravenous injection of from 3 to 4 cc. of a 40 per cent solution of methenamine and from 16 to 17 cc. of a 40 per cent solution of dextrose. The injections were given daily or every other day. Patients received a milk diet, an occasional mild laxative and a warm bath every other day. Gastric intubation was practiced several times in the course of the disease. The average hospital stay amounted to 20.3 days. There were no instances of transition to acute yellow atrophy, despite the fact that some of the cases were severe and exhibited in the beginning symptoms suggestive of impending acute yellow atrophy. The author concludes that the combined methenamine and dextrose treatment is capable of shortening the course of parenchymatous jaundice and of preventing its passage into acute yellow atrophy.

Determination of Protein Content of Blood of Patients with Nutritional Edema. A. G. van Veen.—p. 1747.
Some Diseases of Bones of Foot. S. A. Tahar.—p. 1761.
Leproid Skin Eruptions in Frambesia. M. Soetopo.—p. 1765.

Subclinical Vitamin B₁ Deficiency.—Meyers points out that in the temperate zones the subclinical deficiencies of vitamin B₁ show a much wider range of symptoms than do those of the tropics. He thinks that this is due to the fact that, in the Netherlands East Indies at least, B₁ deficiencies are relatively uncomplicated and chiefly of exogenous origin, whereas in European countries and in the United States these subclinical deficiencies are often caused by alcoholism and chronic diseases of the intestinal tract and are complicated by an atypical form of pellagra. The author investigated the vitamin B₁ excretion in the urine of fourteen healthy Javanese laborers before and after the subcutaneous administration of vitamin B₁. Attention was paid also to the diuretic effect of vitamin B₁ and to its influence on the increase in blood pressure after epinephrine. The results of these investigations could be compared with observations on three healthy "prepared" persons who had received a diet with a high vitamin B₁ content and on three patients with beriberi. The daily excretion of vitamin B₁ in the healthy laborers varied between 0 and 63 micrograms. After the injection the excretion varied between 2 and 50 per cent (in most cases between 10 and 30 per cent). One of the three healthy "prepared" persons showed excretion values of the same order as did the patients with beriberi. In nine of the fourteen laborers the administration of vitamin B₁ had a diuretic effect. However, there was no clear correlation with the vitamin B₁ excretion values. This vitamin has the properties of a true diuretic. In three of eight healthy persons the increase in systolic blood pressure after epinephrine became much stronger after vitamin B₁ had been administered. The same was observed in the patients with beriberi but in none of the three "prepared" persons. Thus this vascular reaction proved to be helpful in determining deficiency of vitamin B₁ where other means had failed; but no correlation could be detected with the excretion of vitamin B₁ in the urine. The excretion of vitamin B₁ in the urine by itself often does not produce figures sufficiently unequivocal to judge whether deficiency exists or not.

INDUSTRIAL HEALTH AND NATIONAL DEFENSE

LEVERETT D. BRISTOL, M.D., DR.P.H.
NEW YORK

An adequate national defense requires a vigorous health offensive! Stimulated by the launching of the nation's defense program, the organized medical and public health professions have been quick to realize the importance of the contributions which they can make to health preparedness. The mobilization of the medical profession for any emergency that may arise has been successfully inaugurated with the appointment of a National Committee on Medical Preparedness by the American Medical Association.

Man power is now the greatest need both of industrial production and of military defense. Adequate man power is dependent on the highest type of mental and physical fitness; nor should the health of women workers be forgotten in these times, in view of their important contributions to industrial production and operation and their possible substitution for men in times of serious national emergency. The speed-up of production and manufacture, the development of new material and methods, the increased employment of new workers unused to the hazards of industry will require new industrial health routines and regulations, more intensive study and research in the field of occupational diseases and industrial poisons and the extension and improvement of all health and safety education. To speed the work but to spare the worker should be our aim!

GENERAL HEALTH PREPAREDNESS

Industrial health preparedness in the United States is only one phase of a general health preparedness program, although from the standpoint of national defense industrial health undoubtedly should command first attention, since it involves our adult civilian population of productive workers and the enlisted land, sea and air forces of the country, on all of which successful national defense in times of emergency must depend. The first essential in our countrywide public health program during these times of preparation for adequate national defense is a thorough scanning of our organized medical and health machinery to be sure that important matters of coordination and administration are provided and that there are no gaps or weaknesses in federal, state, county or city health administration or in public and private medical facilities. Moreover, during times of temporary national emergency, centralization of medical and public health authority is required.

Read before the International Society of Medical Health Officers,
Detroit, Oct. 7, 1940.

INDUSTRIAL HEALTH

During the World War of twenty-five years ago I had the privilege of serving as commissioner of health of one of the New England states. Our work was closely integrated with that of the federal Public Health Service during the war period. In fact, the Surgeon General of the Public Health Service suggested that all state health officers remain at their posts in order to cooperate in the federal wartime health program. The one thing I do not remember as an important part of our federal-state program at that time was industrial health or industrial medicine. The fact is that private industrial medicine in this country was then only in "swaddling clothes" and one or two industrial hygiene units in state governments had only just been born. The Division of Industrial Hygiene of the United States Public Health Service and the Section on Industrial Hygiene of the American Public Health Association are only a little over 25 years old, having been created in 1914. The American Association of Industrial Physicians and Surgeons also is but 25 years old, while the American Industrial Hygiene Association held its first annual meeting this past June. It has been only during the past three or four years that bureaus of industrial hygiene have been rapidly extended in health departments of various states and cities, under the excellent leadership of the United States Public Health Service. Only since 1937 has the Council on Industrial Health of the American Medical Association been operative in cooperation with committees or activities on industrial health in thirty-four state medical societies, most of which have been organized during the past three years. In other words, the whole specialty of industrial health as we know it in this country is at the present time only a little over 25 years old and has developed almost entirely since the World War.

As a part of a national defense program, it becomes evident from the foregoing facts that industrial physicians and industrial hygienists of this country have little in the way of precedent or wartime experience on which to base their efforts, unless it be, to some extent, the recruiting experience and a few engineering experiences during the World War. As a matter of record, it may safely be predicted that the present national preparedness program will be to industrial medicine and industrial hygiene in the United States what the World War was to the greater stimulation of interest and plans in the field of social hygiene. It is particularly to be hoped that the present plans for national defense will result in more active cooperation between industrial medical departments and local and state health departments and medical societies. One concrete achievement of such coordinated efforts might be a much needed national plan for standardized recording and reporting of industrial morbidity and mortality, particularly of occupational diseases.

PRIVATE INDUSTRIAL MEDICINE

One of the most important problems common to industrial medicine and military medicine is that of traumatic surgery. Industrial medicine's so-called parents might be said to have been (1) traumatic injuries of workers and (2) workmen's compensation laws. In any national preparedness program much should be done to increase the facilities for teaching traumatic surgery in our medical schools and in developing postgraduate instruction for practicing physicians through county and state medical societies and military organizations. In this connection, much of the leadership in promoting and teaching traumatic surgery might be available from those industrial surgeons who even during peace time have become experts in the fields of traumatic surgery and first aid treatment of accidents and infections.

Industrial medicine, even in a national defense program, must be preventive and educational as well as reparative, reconstructive and curative. It must concern itself with nonoccupational as well as occupational diseases. Industrial physicians will have important parts to play in the national defense program from the standpoints both of (a) the physical and mental fitness of civilian workers and enlisted forces and of (b) the safety and healthfulness of working and training environments.

During the present national emergency, professional facilities must be made available not only for a successful medicomilitary program but also for the continuity of adequate medical care for the civilian working population. In the latter connection it should be stressed that much of the load of responsibility will continue to be carried by individual practicing physicians. The great bulk of industrial medical work is now being carried on by private physicians on a part time basis. One of the first essentials, therefore, in an industrial health preparedness program is to determine all physicians in the United States who are qualified for industrial medical service, with some indication of their experience and special fields, such as administration, physical examinations, first aid, industrial surgery, industrial toxicology and industrial health education.

The possible availability of properly qualified full time industrial physicians and surgeons for special assignments in the federal service should be given careful attention while at the same time acknowledging the fact that as a group the greatest usefulness of trained industrial physicians in a national emergency may be in their remaining at their posts in private industrial organizations. The inauguration of a plan for state and regional consultants on industrial health would be desirable in the interest of better organization and coordination. Such consultants, during the preparedness emergency, might be attached to the United States Public Health Service. Their chief function would be as consultants and coordinators working in cooperation with (a) state and local health officers, (b) state and county medical society committees on industrial health, and (c) industrial medical departments.

The Council on Industrial Health of the American Medical Association at its last meeting expressed its willingness to assist in the development of intensive training on industrial health methods for full time and part time industrial physicians, through its organization of committees in state medical societies. The Council already has acquired information on all major medical agencies interested in employee health and on the avail-

able facilities for undergraduate and postgraduate industrial medical training in the educational institutions of the United States, as well as other data of potential value in an industrial health preparedness program as a part of national defense. A general statement of medical relationships in industry and of industrial medical education appeared in a special industrial health issue of *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* last February.¹ Speaking as a member of the Council, which is a standing committee of the Board of Trustees of the American Medical Association, we would welcome the cooperation of the International Society of Medical Health Officers in all matters pertaining to the advance of industrial health in the United States.

OBJECTIVES OF INDUSTRIAL AND MILITARY MEDICINE

The basic objectives of both industrial medicine and military medicine are much the same, namely:

1. To ascertain, by examination, the fitness of individuals for civilian work or military service, and to place individuals in activities consonant with their physical and mental assets and liabilities.
2. To maintain and improve the health and efficiency of those already employed or in government service.
3. To educate the worker or the enlisted man on matters pertaining to personal hygiene.
4. To reduce lost time and absenteeism from industrial occupation or military duty because of illness or injury.

To reach these objectives of either industrial or military medicine a definite plan or program must be formulated under suitable medical direction, with the employment of qualified physicians, surgeons, nurses and other specialists and technicians as may be needed. Medical offices and adequate emergency, dispensary and hospital facilities are essential. Suitable physical examination and medical records are necessary. Medical supervision also should include all matters of general sanitation and environmental hygiene, with the assistance of specialists, such as engineers and chemists, as may be required.

PHYSICAL EXAMINATIONS

Of primary importance among the objectives common to industrial and military medicine are physical examinations. The scope or extent of preplacement examinations must be based largely on the character and general conditions and needs of the industry or the military assignment. Such examinations may vary all the way from a very brief, superficial physical inspection to a detailed medical examination of an hour or more. We shall have to strike some midground as far as the average examination is concerned. We certainly want to make examinations that are worth something; on the other hand, there is a limit that may be reached as to their practicability from the standpoints of time and expense. Physical tests of employees during the national defense emergency might possibly be based on requirements and record forms previously agreed on jointly by military and industrial authorities. This would be the means of saving time and in the interest of standardized procedures and records in the proper placement of workers in civilian or military positions.

The purpose of medical examinations should not be to keep people out of work or out of military service but rather to know what the actual conditions are and to make certain that the individual does not take up a job for which he is not fitted. Time will not permit of a detailed account of the various types of physical

1. *Industrial Health*, J. A. M. A. 114: 573 (Feb. 17) 1940.

examination procedures and forms of examination classifications or of acceptance and placement standards and causes for rejection. These subjects have been extensively covered from time to time in pamphlets and bulletins of various voluntary and government organizations and are available to those interested in the subject of physical examinations.

As interest grows in the subject of mental hygiene, which underlies the whole realm of physical health and safety, more and more attention must be given to mental and nervous system examinations in connection with routine physical appraisals of civil and military groups. Bad mental hygiene of individuals and masses to a large degree is responsible for much industrial unrest and even for lowered morale in armed forces. To obviate this the promotion of a sound program of mental health in industry and among enlisted forces is the only alternative; this, in turn, can be built only on knowledge obtained through satisfactory mental inventories of employee or recruit groups.

Of all measures of industrial health preparedness from the standpoint of national defense there is none more important than the periodic health examination of individuals in working groups. Such examinations should serve not only (a) to guard the health of civilian employees in industry, particularly those in the so-called war industries, from excessive fatigue and the possible ill results of speed, pressure and special hazards associated with national preparedness but also (b) to maintain a high level of physical and mental fitness in those private industrial "reservoirs" which at any time might have to be drawn on for government service. Business organizations may thus contribute to national defense by encouraging such health examinations among their employees. Physical examinations, both initial and periodic, fall short of their full value unless followed up with programs for the control and correction of incipient diseases and impairments which are found. Moreover, these examinations, above all, should be considered as important educative experiences.

PUBLIC INDUSTRIAL HYGIENE

Prior to 1936 there were in the United States only five state departments of health and two or three state departments of labor conducting industrial hygiene activities, and even these activities were of limited nature. As of 1940, a total of thirty-nine state and local industrial hygiene units have been established in twenty-nine states and two territories, mostly in departments of health. Some of these are of very recent creation and have only skeleton organizations. There is great need that these be strengthened as rapidly as possible as a part of the national industrial health preparedness program. Moreover, additional industrial hygiene units should be organized without delay in the remaining states and territories and additional local governments, particularly of the larger cities. Steps should be taken to make possible the financing of these industrial hygiene units by state and local appropriations. At present nearly 80 per cent of funds budgeted for public industrial hygiene is contributed by the federal government. During the present emergency, additional funds should be provided to the Public Health Service to train additional industrial hygiene personnel. Care should be taken to emphasize that such industrial hygiene activities are properly the function of health departments and to discourage steps taken in a few localities to develop such essential health services in agencies other than health departments.

CONCLUSION

It may be stated that industrial physicians and industrial hygienists, like medical public health officers, are ready and willing to serve their country in this preparedness emergency. Industrial health work should be a strong arm in national defense, particularly in the preservation of expert workers and assisting in the development of additional skilled workers. Reducing lost time due to occupational and nonoccupational illness and accidents and cutting down excessive exposure to injurious materials are part of the industrial health program which will be conducive to maximum national effectiveness and production. It is particularly necessary that studies be made to determine unfavorable environmental factors in the production of war equipment and munitions. The business employer or the governmental unit that considers reducing its industrial health program at this time, because of what at the moment may seem to be more important activities, is most unwise. As a matter of fact, the needs of national defense require a strengthening and broadening of the entire industrial health program all along the line from private industry to local, state and federal jurisdictions. In this significant period of rearmament, during which our chief defense will be our industrial skill, let us be sure that we place first on our list the health and safety conservation of our industrial workers.

195 Broadway.

OPPORTUNITIES FOR PHYSICIANS IN INDUSTRY

THOMAS L. SHIPMAN, M.D.

LYNN, MASS.

From the beginning let it be remembered that this paper is not concerned primarily with "opportunities for industrial physicians." I shall principally consider the opportunities which await the rank and file physician, the general practitioner, in his contact with industry. Let it also be remembered that no facts or percentages which have been gathered in the many studies in this field can be regarded as strictly accurate; no specific figures exist, and it is possible to regard percentages given as indicating only general trends. What is this "industry" that is discussed so casually? Industry is composed of approximately 18 or 20 million human beings who are scattered in groups of various sizes throughout the length and breadth of the country. These individuals are engaged in every conceivable type of occupation and they are working in every conceivable environment. The Council on Industrial Health has listed 241 establishments which employ more than 2,500 men and women, and these larger establishments employ only 10 or 11 per cent of our total 18 or 20 million workers. Sixty-two per cent of this enormous number of individuals are working together in little groups of 500 or less. What sort of medical care are these people getting at the present time? According to the American Medical Directory there are approximately 1,400 or 1,500 physicians who either limit their work to the industrial field or who otherwise regard it as their special interest. The fact becomes at once apparent that the majority of American industrial workers receive medical care from physicians whose interest in this industrial work is, to say the least, secondary.

Read before the Section on Preventive and Industrial Medicine and Public Health at the Ninety-First Annual Session of the American Medical Association, New York, June 13, 1940.

The physicians serving industry may be divided into three broad classifications. In the first group are full-time industrial physicians, some of them actively engaged as plant physicians, some working with insurance companies, others who regard themselves as consultants, but all of them choosing to consider industrial medicine or surgery, or both, as their particular specialty. The second group includes doctors who serve industry on a part-time basis. Ordinarily these are doctors with private practices of their own in the field of general medicine or surgery. They have, however, definite understanding and interest in the medical problems in industry, and they ordinarily have some sort of a working agreement with one or more particular industrial groups. I know of one man who could be regarded as a good example of this type: he is the works physician for a fairly large industrial plant during the morning but in the afternoon, unlike the leopard, he does change his spots and emerges as a pediatrician. So far he has refused to confess to me which he regards as his vocation and which his avocation.

In the third category must be included almost all the remaining doctors in the country. Today there are but few doctors who do not occasionally encounter problems which in one way or another should be classified as industrial. Unfortunately the industrial connection in these problems frequently goes unrecognized; but it is possible that one patient's continued headaches result not from chronic sinus trouble or eyestrain but from a mild and repeated exposure to carbon tetrachloride. How about the overworked executive in an industrial concern? If the family physician who is advising this man to take things easy would cooperate with the plant physician he would have the satisfaction of knowing that his suggestions would be carried out. How about that obscure case of eczema which seems to be defying both diagnosis and treatment? The consideration of the substances with which the man works is most certainly of prime importance, of just as great importance as arranging for changes in the type of work which a girl does in the early months of her pregnancy. So many of the general practitioners throughout the country blindly close their eyes to the possibilities of cooperating with industry that they really represent a greater problem than the unhappy few who admittedly are ready to put the blame for every disorder on the patient's work.

That this state of affairs should exist is hardly to be wondered at if one thinks for a moment of the training which the average physician receives in matters pertaining to industrial medicine. In the academic year just closed fifty-two medical schools were listed as providing required instruction in industrial hygiene. On the average, from four to five hours of lectures is devoted to this work and less than half of these schools provide any field trips, although many of them do require that the students should prepare some sort of a sanitary survey. Twelve schools were listed as providing elective or postgraduate courses in industrial hygiene and nine other universities are equipped to provide advanced instruction in this field. Fortunately, this list is growing each year; ten and fifteen years ago, however, the list was painfully brief. This means of course that, except for recent graduates of these fifty-two medical schools, an enormous number of doctors have never received any form of instruction whatever relating to industrial matters. As I look back on my own exposure to industrial hygiene in medical school I realize how completely it failed to place the

specialty of industrial medicine before the students as an attractive possibility for a future career. It was much like being served a plate of cold unseasoned spinach in a restaurant famous for the elegance of its cuisine. Industry and the medical schools must get together if the students are to see the field of industrial medicine in its proper perspective. One can even visualize the time when some forward looking hospital will make arrangements with an industry whereby the interns will actually spend a specified time working in and for that industry.

The existing educational institutions can take care of training well equipped young men prepared for full-time work in industry at the present rate of demand. Up to the present, however, that demand has not been nearly large enough, and there are even now large industrial concerns which seem to be perfectly satisfied with second rate medical care for their employees. I know of one industrial plant, employing approximately 14,000 men, where the medical staff consists of one full-time physician. Preemployment examinations in this plant are done by a man who really started as a first aid worker; he told me rather proudly that he could do over 300 physical examinations a day! A situation of this sort certainly seems to be out of step with the general trend. According to the National Industrial Conference Board, the per capita cost for medical care in industry between 1915 and 1938 rose in almost a steady curve from 88 cents to \$6.15. I cannot feel that industry has become so paternalistic and altruistic that it would continue such a policy without expecting something in the way of return on that investment.

While on the subject of finance one should not attempt to dodge the issue that in the budget of any medical department in industry salaries probably represent the largest item. It is not too difficult to arrive at a wage rate for a nurse or x-ray technician which will correspond reasonably well with the general level existing in the community. As to how much a full-time physician in industry is worth, there seems to be a decided lack of unanimity. If a full-time physician in industry contents himself with bandaging fingers and dispensing pills, he probably is not worth much to that industry, but if he is willing to tackle his job with the same enthusiasm, the same level of intelligence and healthy curiosity shown by the specialists in any other line, his financial reward should be in proportion. Industry must prepare to pay for a specialist if it wishes the advice and services of a specialist. If industry pays for a finger bandager or a pill pusher, that is just what industry will get.

To the operator of the small industry the establishment of a high powered medical department with a full-time physician is obviously out of the question. How is the manager of the small concern to provide adequate medical care for his employees without a disastrous financial outlay? As I see it, there are two solutions to this problem: in the first place, the services of a true industrial physician could be shared with other concerns. This can be and has been done with great success, and I need only refer the unbeliever to the experience of Dr. Frank Griffin in Toronto as reported in the *Canadian Public Health Journal* for November 1939. Here one can read how one physician was able to take over the medical care in several small plants, do the physical examinations, arrange for nursing service and oversee the general plant hygiene. I know of several situations in this country where a similar arrangement is in operation. The other solution which can be used in

any community, regardless of its size, is to make use of the general practitioner who is already on the job. Almost all industrial concerns, especially the small ones, seem to have particular physicians on whom they call when emergencies arise. It may be that the physician called is the only one in town. The point which I wish to emphasize is that in far too many cases the poor physician is not consulted until after the accident has occurred. I have no desire to turn every doctor into a safety engineer; nevertheless what a superior arrangement it would be for all concerned if that small industry and the doctor could get together on a plan for regular medical supervision of all matters pertaining to the health of the employees; let them start regular pre-employment examinations and, even better, periodic examinations. Details of this plan would, of course, have to be adapted to the particular circumstances. It might mean one morning or part of a morning a week for physical examinations and one morning every month or so for a general plant inspection. I am sure that even a small industry would reap a generous return from any money expended in this direction. Here, I feel, lies the real opportunity for physicians in industry. Here lies the way of bringing improved medical care to the greatest number of individuals.

Obviously an industry must exercise a certain amount of judgment in naming the doctor to carry out a program of this sort. I am convinced that the majority of general practitioners who are honest would welcome a closer intimacy with industry. They will produce the argument, however, that they have no training in industrial work and would not have any idea how to go about it. Already twenty-nine states in their state governments have set up departments which are interested primarily in industrial hygiene. The state medical associations are a jump ahead and thirty-four of these societies now have committees on industrial health. These various groups are continually increasing the scope of their activities as well as increasing in number. These are the groups that stand ready to assist the general practitioner as he embarks into the somewhat bewildering and complex field of industrial medicine. Of course there are opportunities for physicians in industry. They exist in nearly every consulting room in the country. They exist in nearly every industry in the country, large or small. They exist somewhere in the family life of the majority of the people in this country. They await only recognition, but they must be recognized jointly by industry and by the medical profession. It can be only when these two groups join hands that these opportunities can be fully realized. A lot of missionary work and a lot of pioneer work remain to be done.

920 Western Avenue.

ABSTRACT OF DISCUSSION

DR. M. N. NEWQUIST, New York: These opportunities exist primarily for rendering an unbiased constructive medical service to the employer and to the employee and they should not be converted into a means for soliciting patients. Fortunately there has been very little abuse of these opportunities. The opportunity to render medical service in industry should be considered in its preventive, administrative and curative phases. Include visits to the plant at regular intervals, participate in the control of sanitation and in the administration of benefit plans where health is involved. It is a job in "human engineering" from start to finish. I know of no better human engineer than the doctor. Progress in industrial medicine will continue to be slow until more employers provide the opportunity. Doctors cannot go into a plant uninvited.

On the other hand, employers are not willing to embark on a health program without being reasonably assured that it will justify its cost. Actual demonstrations by physicians that good industrial medical service will pay dividends is the best way to educate employers. A "speed up" in the progress of industrial medicine is in the offing with the more widespread teaching by medical schools, the American Medical Association and other medical organizations of industrial medicine in all its phases including industrial toxicology, occupational disease and engineering methods for their control. The practice permitting first aid men and other nonqualified persons to make physical examinations of employees should be discontinued. The general practitioner will continue to play an important role in serving the numerous small industrial establishments widely scattered throughout the country. He can cope with most of the medical situations which arise in the average plant. In the relatively few obscure problems it is the part of wisdom anyhow to call in a qualified consultant. If employers would abandon the "cash and carry" method for obtaining medical service and would charge their plant physicians with appropriate responsibility for engineering the health of their human machinery, the whole complexion of the field of industrial medicine would assume a more healthful hue.

ACUTE APPENDICITIS IN CHILDREN

A CLINICAL STUDY OF MORE THAN 1,000 CASES

EDWIN M. MILLER, M.D.

EGBERT H. FELL, M.D.

CHICAGO

CLAYTON BROCK, M.D.

ST. LOUIS

AND

M. C. TODD, M.D.

CHICAGO

There is probably no one subject in the entire field of surgery that has aroused more widespread interest among the public and the members of the medical profession than that of acute appendicitis and its complications. Yet the very fact that at this session the American Medical Association is devoting a symposium to this topic, even though more than half a century has elapsed since the pioneer work of Reginald Fitz, seems proof enough that there remains a good deal of uncertainty, at times, as to methods of management of the patient with appendicitis. Much progress, nevertheless, has been made and is being made, especially as the result of careful clinical studies in large series of cases. Too often, however, papers have been written on evidence obtained by a review of hospital records rather than from personal observation of patients, and therefore the conclusions drawn have sometimes not been as reliable as they should be. Too often, also, statistics have been published as to the effectiveness of treatment without clear differentiation between perforations of the appendix which clinically have remained localized (with a definitely palpable mass) and those which have obviously involved the open peritoneal cavity.

We submit here the result of what we consider a careful personal clinical study of well over 1,000 cases of acute appendicitis and its most frequent complications observed by us at the Children's Surgical Ward of the Cook County Hospital, Chicago, during a little more than four years, hoping that from it certain conclusions

From the Surgical Service of the Cook County Hospital and Rush Medical College.

Read before the Section on Surgery, General and Abdominal, at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

may be drawn which will be helpful in clarifying the still existing uncertainty as to reliable indications for and against operative intervention.

CLASSIFICATION AND TREATMENT

During the past twenty-odd years of surgical practice it has gradually become apparent to us that, from a clinical point of view, patients with acute appendicitis and its most common complications, whether children or adults, fall naturally into one of three fairly clearcut, fairly well defined groups, and we feel that it is highly important for one to decide, or at least to attempt to decide, into which of these each patient belongs, as this decision may materially influence the course of treatment.

GROUP 1.—This group comprises all patients who are obviously suffering from an attack of acute appendicitis before the stage of perforation. It seems hardly necessary here to elaborate in detail either on the usual "textbook" picture or on the difficulties that may arise in making a diagnosis when the atypical case is encountered. Suffice it to say (for the purpose of this discussion) that we believe it to be the consensus today that appendectomy as soon as the diagnosis is made is the treatment of choice, except for those patients in whom the attack is definitely subsiding. In our study there were 629 patients in this group, all of whom were successfully operated on without a single death. Would that every patient when first seen by the surgeon could be included in this group.

GROUP 2.—In this group a longer duration of symptoms is noted. The characteristic clinical observations are obviously those associated with a perforation of the appendix against which there has been set up from the time of perforation an adequate local defensive mechanism. A careful history will usually show that the patient has been sick for several days, perhaps a week or ten days or even longer. He does not as a rule appear desperately ill. The fever may be fairly high and the leukocyte reaction well marked, but he does not have an anxious expression, nor is he suffering intense pain. On abdominal examination with the patient relaxed and the thighs held in flexion, one can make out by palpation the margins of a definite mass, varying in size from that of a walnut to that of an orange or perhaps even a small grapefruit and varying considerably also in position. Though it usually occupies the right lower quadrant, it may be felt well into the right flank; sometimes it is in the left lower quadrant, and not infrequently it is deep in the pelvis, where it can be made out only with the finger in the rectum. Occasionally it is so deeply situated in the main abdominal cavity and so covered by large tense abdominal muscles that its presence is made certain only after complete relaxation induced by an anesthetic, and in extremely rare instances it may not be discovered until after the incision has actually been made and the walled-off process seen with the naked eye or felt with the examining finger. The point we wish to make is this: Whatever its size, whatever its position and however its presence may be detected, it represents pathologically a slow leak from the appendix, which has become effectively sealed off from contact with the open peritoneal cavity.

As to the treatment of the patient in this group, we are well aware that there is still a considerable difference of opinion even among competent surgeons. Many feel that the majority, if not all, of these so-called appendical abscesses should be drained early, and some even go so far as to advocate a serious attempt at removal of the

appendix at the same time. With this attitude we cannot agree; such a policy is neither safe nor necessary. It is not safe, because, if between the wall of that palpable mass and the parietal peritoneum there are normal loops of bowel, spreading peritonitis is apt to be produced by the attempt at drainage; it is not necessary, because in the vast majority of cases the mass will spontaneously disappear. Our study furnishes ample evidence to prove that with more than 90 per cent of these patients careful observation over a period of days will reveal a gradual improvement in the clinical picture, a gradual reduction in the temperature and the leukocyte count, a progressive diminution in the size of the inflammatory mass and, finally, after perhaps ten days to four or five weeks, its complete disappearance, as far as one can tell by physical examination. We advise these patients to return to the hospital after approximately three months, when they are feeling perfectly well. The appendix may then safely be removed, no matter how densely it may have been involved in adhesions. Only a few cases in this group (in our experience) will take the opposite course, with a progressive aggravation of the clinical picture and a progressive enlargement of the palpable mass to the stage at which it represents unquestionably a real "abscess." Under these circumstances it will have definitely tried to point somewhere, either anteriorly against the parietal peritoneum, where it can easily and safely be drained through what amounts to an extraperitoneal approach, or downward more deeply into the true pelvis, where it can be felt as a soft bulging mass against the anterior wall of the rectum and where it has a fair opportunity to break through spontaneously without the aid of surgical intervention. In our study, 228 patients have been classed in this group. Of these, twenty-five were operated on for drainage, but I am sure that for some of these the procedure was not necessary, and a longer period of observation would doubtless have shown this to be true. All of the others (203) were given the benefit of watchful conservatism, and of these 198 recovered, a mortality of only 2.5 per cent.

GROUP 3.—In contradistinction to those in groups 1 and 2 the cases included in group 3 represent acute perforations of the appendix into the open peritoneal cavity, perforations against which there has at no time been established an adequate defense. Pathologically speaking, in many of them the condition is of the obstructive type, with a large fecal stone, and the perforation is grossly of considerable size. To use a crude simile, it is not unlike a sudden "blowout" of a tire, in contrast to a slow leak. Often the streptococcus is the predominant organism, and often too the patient's resistance to infection is low. As a rule he looks very sick; there is a pinched, anxious expression; the tongue is dry; the pulse is fast, and the fever and leukocyte count are variable. The knees are held in flexion; the breathing is thoracic; the abdomen is distended; on palpation one finds the muscles everywhere tense, and there is more or less general tenderness, at times even in the left flank. The whole picture is suggestive of spreading peritonitis.

What shall we say as to the care of this patient? Has he a better chance to recover if he is not operated on and use is made of the so-called Ochsner method of treatment, with Fowler's position, adequate physiologic solution of sodium chloride and dextrose given by vein and under the skin, restriction of fluid by mouth, a Levine tube for relief of distention, and administration of mild sedatives, in the hope of diminishing

peristalsis and perhaps of localizing the spreading infection? Without question, a number of surgeons hold this view (many of prominence among them), and it would take a bold critic to claim that such measures are not of great value. But we would ask these surgeons: Would they apply this conservative regimen to all patients in this group or to only a few? And if to only a few, to which ones? Would they apply it only in the late stages or in the early ones as well? Would they apply it only to patients with evidence of widespread involvement of the peritoneum or to those also in whom the infection is apparently limited? We have often heard it said that if the patient has been sick for less than forty-eight hours he should be operated on; if for more than forty-eight hours, operation will be withheld. Some place the limit of time at even less; others would arbitrarily fix it at fifty-six hours or even more. To these points of view we humbly and in all seriousness express our belief that no physician, however wise he may be, can hope to judge accurately the rapidity of pathologic changes; no physician, even from the most carefully obtained history (especially with children) can be certain as to the exact duration of the attacks of appendicitis (which is so often preceded or accompanied by other things which cloud the picture); no

finally, use of a measure which has lately been emphasized by Gatch and his associates and has been used by us empirically for a long time, i. e. replacement of lost plasma protein (both before and after operation) by means of blood transfusion.

As to the technic of the operative procedure for patients in this group, perhaps little need be said. The McBurney incision is almost always employed. Cultures are always made of the free pus when the peritoneum is opened. The Poole suction tip has practically replaced the use of sponges in the abdominal cavity. The perforated appendix is delivered with a Babcock forceps, which encircles its wall; the stump is always ligated with catgut and whenever possible is buried beneath a catgut purse string. As to the matter of drainage, there is still considerable difference of opinion among our own group as to its value. Some are bold enough to close these incisions without a drain. (We have had occasion several times to open these incisions later to allow free evacuation of foul-smelling pus, and in one instance, in which a diffuse anaerobic phlegmon of the entire right abdominal wall had developed subsequent to a tight closure, we were obliged to reflect enormous flaps of skin to expose the area involved to the open air.) A few prefer to close the peritoneum

physician can always be sure of the exact time when the perforation has occurred, nor can he be certain, even by the most painstaking examination, of the extent of involvement of the peritoneum by the spreading infection. If these statements are true, why should one allow such unreliable criteria as these to influence one as to the decision for or against surgical intervention?

The answer is that one should not. We are of the firm opinion that those who advocate a conservative course with patients in this group are wrong, because it appears to us that the essence of the treatment should consist in removal of the ruptured appendix, which closes the leak through which a constant stream of infected material is being fed into the peritoneal cavity. Just as with an open perforation of a duodenal or a gastric ulcer, the essential thing is to close the opening as soon after it occurs as possible. With us there has been, therefore, an ever increasing tendency over a period of years to apply this policy of immediate operation to practically all patients in this group, no matter how much time seems to have elapsed since the onset of illness, and we are more and more convinced of the wisdom of this course. We do not, however, wish to give the impression that when we use the term "immediate operation" we mean that the patient is sent from the admitting room to the operating table, for long since we have seen the value of adequate preparation, with restoration of the electrolyte and fluid balance, relief of distention as far as possible with a Levine tube and,

and drain only the incision itself. We believe, as do most other surgeons, that it is not mechanically possible completely to drain the infected peritoneal cavity by the introduction of one or more tubes, yet we continue to use drainage in every case of perforation, always employing drains of the soft cigaret type and always placing them as near the source of the infection as possible. Especially do we feel that they are of value when the perforation has occurred behind the cecum, because they may help to prevent an ascending infection in tissues not protected by peritoneum and thus minimize the likelihood of a subphrenic abscess.

With what success has this regimen been rewarded? A glance again at the accompanying table will show that in this period of a little over four years 306 patients have been classed in group 3. Of these, only twenty-five (8 per cent) were treated conservatively, with a mortality of 80 per cent, whereas 281 (90 per cent) were given the benefit of "immediate" operation, with 242 recoveries (mortality, 12.8 per cent). It will also be noted that in the past two years all patients were operated on, no matter how much time had followed perforation.

CONCLUSIONS

1. Immediate appendectomy is indicated in all cases of acute appendicitis before perforation unless the attack is clearly subsiding.

2. When the clinical evidence shows that the appendix is ruptured and the infection is definitely localized

(demonstrable by a palpable mass), a conservative course is indicated. Only a few patients will need surgical drainage.

3. In all cases in which spreading peritonitis is present without evidence of localization, it is a wise plan to remove the source of the infection as early as possible, institute proper surgical drainage and make every effort postoperatively to restore to the circulating blood whatever elements have been reduced as the result of the infection.

THE MORTALITY FROM ACUTE APPENDICITIS IN THE JOHNS HOPKINS HOSPITAL

EDWARD S. STAFFORD, M.D.

AND

DAVID H. SPRONG JR., M.D.

BALTIMORE

It is well known that death seldom follows the competent removal of an acutely inflamed but unperforated appendix.¹ At present, however, surgeons disagree as to the proper treatment of patients having acute appendicitis with one or more complications. Our own uncertainty led us to study the results of the treatment of acute appendicitis as carried out in the Johns Hopkins Hospital.

In the surgical service of the Johns Hopkins Hospital patients considered to have acute appendicitis in any stage of the disease are subjected to immediate operation. From Sept. 1, 1931, to Sept. 1, 1939, 1,317 of these patients had acute appendicitis. All cases in which there was no gross perforation of the appendix are classified under simple acute appendicitis. All those in which perforation of the appendix was found at operation (except those in which rupture was caused by handling during operation) are divided into two groups:

1. Appendicitis with perforation and abscess formation.

2. Appendicitis with perforation and peritonitis.

No attempt has been made to distinguish between "local," "spreading" and "generalized" peritonitis. We agree with Ladd,² who stated that "no surgeon really

were found to have perforation of the appendix by the time they sought treatment in this hospital and that it was this group in which the deaths occurred. Although 90 per cent of these patients recovered, many seemed clinically just as ill on admission as some who died. In an effort to find out whether it was the treatment employed at this hospital or some other factor which was responsible for the different outcome, we have made a study of the forty-eight fatal cases.

TABLE 2.—Chief Causes of Death

Cause of Death	No. of Cases	Autopsy
Direct complications of appendicitis		
Generalized peritonitis	13	11
Pylephlebitis	4	2
Septicemia	1	0
Inadequate treatment	14	9
Extra-appendiceal complications		
Cerebral accident	1	0
Pulmonary embolism	3	2
Pneumonia	4	2
"Poor risk" patients	4	3
Cause of death uncertain	4	2
Total	48	31

In table 2 we have listed the chief causes of death. These fall into several well defined groups (tables 3 to 9 inclusive). Postmortem examination was made in thirty-one of the forty-eight cases.

TABLE 3.—Group 1 (Death from Acute Generalized Peritonitis Less than Seventy-Two Hours After Operation)

Case	Race, Sex, Age	Duration of Symptoms	Operative Diagnosis	Postoperative Course, Hours	Autopsy
1	W ♂ 2	36 hr.	Peritonitis	20	Generalized peritonitis
2	W ♀ 2	5 days	Peritonitis	30	Generalized peritonitis
3	W ♂ 2	4 days	Peritonitis	36	Generalized peritonitis
4	C ♀ 6	3 days	Peritonitis	12	Generalized peritonitis
5	C ♂ 7	3 days	Peritonitis	12	Generalized peritonitis
6	C ♂ 8	4 days	Peritonitis	70	No autopsy
7	C ♂ 9	3 days	Abscess	44	Generalized peritonitis
8	C ♂ 21	3 days	Peritonitis	40	Generalized peritonitis
9	C ♂ 41	7 days	Peritonitis	16	Generalized peritonitis
10	C ♀ 47	10 days	Peritonitis	6	Generalized peritonitis
11	C ♀ 48	7 days	Peritonitis	12	No autopsy
12	C ♂ 50	5 days	Peritonitis	60	Generalized peritonitis
13	C ♂ 50	14 days	Peritonitis	12	Generalized peritonitis

Material for culture was taken in a routine manner both at operation and at autopsy. Colon bacilli and streptococci were commonly found, but *Clostridium welchii* was found only twice. It is interesting to note that ten of these thirteen patients were Negroes.

It is not known why some patients die of peritonitis, whereas others, with apparently the same kind of infection and degree of illness, recover. In only one of these cases was there any localization of the peritonitis. The resultant spread of the peritonitis in this case may possibly be ascribed to the operative procedure.

TABLE 4.—Group 2 (Death from Pylephlebitis with Multiple Abscesses of the Liver and Septicemia)

Case	Race, Sex, Age	Duration of Symptoms, Days	Operative Diagnosis	Postoperative Course	Autopsy
1	C ♂ 11	5	Abscess	36 days	Pylephlebitis; multiple liver abscesses; septicemia
2	C ♂ 34	4	Peritonitis	20 days	No autopsy
3	W ♀ 56	6	Abscess	67 days	Pylephlebitis; multiple liver abscesses; septicemia
4	W ♀ 58	5	Peritonitis	48 hr.	No autopsy

TABLE 1.—General Summary of Results

Condition	No. of Patients	Deaths	Per Cent
Simple acute appendicitis	838	0	0
Appendicitis with perforation and abscess	283	20	7.06
Appendicitis with perforation and peritonitis	196	28	14.23

knows how diffuse the process is unless he has done a very improper operation." Table 1 summarizes the results.

It will be seen from this table that more than one third of the patients suffering from acute appendicitis

From the Department of Surgery, the Johns Hopkins University School of Medicine.

Read before the Section on Surgery, General and Abdominal, at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

1. Johnson, L. W., and Boone, H. R.: The Navy and Appendicitis, U. S. Nav. M. Bull. 35: 41 (Jan.) 1937. Bliss, R. W., and Heaton, L. D.: Appendicitis in Army Service: Report of 2,100 Cases, Ann. Surg. 107: 242 (Feb.) 1938.

2. Ladd, W. E.: Immediate or Deferred Surgery for General Peritonitis Associated with Appendicitis in Children, New England J. Med. 219: 329 (Sept. 8) 1938.

As the first of these patients had severe chills prior to operation, he probably had pylephlebitis before the appendix was removed. The diagnosis of pylephlebitis in the second case was substantiated by laparotomy, which disclosed multiple abscesses of the liver. This patient was deeply jaundiced, and colon bacilli were repeatedly cultured from his blood. The fourth patient was deeply jaundiced on admission.

In group 3, one patient died with peritonitis, septicemia and leukopenia. This patient, a 37 year old Negress, had generalized peritonitis found at operation five days after onset of symptoms. A heavy growth of *Bacillus coli* was obtained from samples of blood taken preoperatively and postoperatively. The marked and persistent leukopenia (leukocyte count, 3,400 to 7,600 per cubic millimeter), with a normal differential count, probably indicated a poor response on the part of the patient to an overwhelming infection. Death occurred five days after operation. Repeated transfusions failed to influence the leukopenia. There was no autopsy.

TABLE 5.—Group 4 (Death from Complications Inadequately Treated)

Case	Race, Sex, Age	Duration of Symptoms	Operative Diagnosis	Postoperative Course, Days	Autopsy
1	C ♂ 8	36 hr.	Peritonitis	5	Mechanical ileus involving lower part of ileum
2	C ♂ 33	4 days	Abscess	5	Mechanical ileus involving lower part of ileum
3	W ♂ 23	4 days	Peritonitis	8	Mechanical ileus involving lower part of ileum
4	W ♀ 10	2 days	Peritonitis	23	Mechanical ileus involving terminal part of ileum; generalized peritonitis
5	W ♂ 9	3 days	Peritonitis	23	No autopsy
6	C ♂ 11	6 days	Abscess	7	No autopsy
7	C ♂ 33	2 days	Peritonitis	10	No autopsy
8	C ♂ 20	48 hr.	Peritonitis	20	Left subphrenic abscess with extension through diaphragm; multiple lung abscesses
9	C ♂ 55	36 hr.	Peritonitis	37	Right subphrenic abscess with extension through diaphragm and into liver; multiple lung abscesses
10	C ♂ 43	8 days	Abscess	45	Left subphrenic abscess with extension through diaphragm; multiple lung abscesses
11	W ♂ 16	5 days	Abscess	26	No autopsy
12	C ♀ 10	5 days	Abscess	25	No autopsy
13	W ♂ 43	2 days	Abscess	72	Rectovesical fistula; cystitis; pyelonephritis
14	C ♂ 20	10 days	Abscess	9	Generalized peritonitis

The most frequent complication in group 4 was mechanical ileus, which caused seven deaths. It is often difficult to distinguish between mechanical and paralytic ileus. The latter commonly accompanies peritonitis and responds well to conservative treatment, whereas delay in the relief of mechanical ileus is fatal. When the surgeon can make the diagnosis of mechanical ileus he is still faced with the difficult problem of dealing with the obstruction. Whether to perform simple enterostomy or to release the obstructed bowel in any given case requires nice judgment. The seven cases of mechanical ileus in this group represent failures. In cases 1 and 2 the mechanical nature of the obstruction was recognized late, and an enterostomy was performed only a few hours before death. The fact that patient 3 had a mechanical obstruction was unrecognized until postmortem examination was made. In cases 4 and 5 the fatalities resulted from the complications of surgical procedures designed to relieve the

obstruction directly. In case 4 a laparotomy was performed sixteen days after the appendectomy. The lower part of the ileum was badly traumatized in freeing dense adhesions, necessitating a resection. This procedure failed to relieve the obstruction and also caused a secondary flare-up of peritonitis. In case 5 a laparotomy with release of adhesions was performed eight days after appendectomy and again two days later. The patient stood these procedures satisfactorily. Disruption of the wound occurred, in the course of which a high loop of jejunum was traumatized by contact with a through and through stay suture, producing a high intestinal fistula. There was no postmortem examination in the sixth and seventh cases, but a review of the clinical record leaves no doubt that the cause of death was an unrecognized mechanical ileus in both instances.

The course of events in the next five cases in this group was almost identical. The patients all did well at first, but later subphrenic abscesses developed, which were not recognized clinically. In each instance the abscess perforated through the diaphragm into the lung, causing fatal pulmonary abscesses. In case 11 there was no postmortem examination but there is little doubt as to what occurred. The patient had had abnormal physical signs at the base of the right lung for several days. Suddenly he began coughing up great quantities of foul pus in which the colon bacillus was the predominant organism. He became cyanotic and rapidly weaker and died in a few hours. Study of the clinical record suggests that patient 12 also had an unrecognized right subphrenic abscess.

In the thirteenth case the bladder was entered in an attempt to drain a pelvic abscess through the rectum. A persistent rectovesical fistula formed and resulted in a fatal ascending infection of the urinary tract. The last patient in this group entered the hospital with urinary symptoms. He was found to have a pelvic abscess lying against the bladder. This was drained through the abdominal wall, no attempt being made to remove the appendix. The patient progressed well for seven days, when generalized peritonitis suddenly developed and he died in forty-eight hours. Post-mortem examination showed the pelvic abscess nearly healed, but there was also a smaller abscess about the perforated appendix in the right lower abdominal quadrant. This untreated abscess had ruptured into the general peritoneal cavity.

In group 5, one patient died as a result of a cerebral accident. This patient, a white woman aged 67, had an appendical abscess at operation ten days after the onset of symptoms. She seemed to be progressing favorably for twenty-four hours after operation, when she suddenly lost consciousness; bradycardia and bradypnea developed, and she died within an hour. There was no autopsy.

TABLE 6.—Group 6 (Death from Massive Pulmonary Embolism)

Case	Race, Sex, Age	Duration of Symptoms, Days	Operative Diagnosis	Postoperative Course, Days	Autopsy
1	W ♂ 75	14	Abscess	14	Thrombi in right pulmonary artery
2	C ♂ 49	3	Abscess	10	Emboli in pulmonary arteries
3	W ♀ 35	8	Abscess	14	No autopsy

All of these patients were convalescing uneventfully until the sudden onset of the fatal complication.

TABLE 7.—Group 7 (Death from Pneumonia)

Case	Race, Sex, Age	Duration of Sym- ptoms, Days	Operative Diagnosis	Postop- erative Course, Days	Autopsy
1	W ♂ 13	5	Peritonitis	4	Bilateral bronchopneumonia, pneumococcus type 2
2	C ♀ 52	3	Peritonitis	6	Pneumonia and atelectasis
3	C ♂ 45	4	Peritonitis	3	No autopsy
4	W ♂ 55	5	Abscess	4	No autopsy

All of these patients appeared to improve for twenty-four to forty-eight hours after operation and then suddenly became critically ill, with clinical signs and x-ray evidence of pneumonia. It is interesting to note that two of the patients were operated on under spinal anesthesia; ether by open drop was used for the third and local infiltration anesthesia for the fourth. These deaths occurred before the introduction of sulfa-pyridine.

TABLE 8.—Group 8 (Death Due to Poor General Condition Prior to Onset of Appendicitis)

Case	Race, Sex, Age	Duration of Sym- ptoms	Operative Diagnosis	Postop- erative Course	Autopsy
1	W ♂ 57	24 hr.	Abscess	4 hr.	Addison's disease; tubercu- losis of both adrenals
2	W ♂ 75	2 days	Abscess	12 days	Diabetes mellitus
3	C ♂ 55	6 days	Abscess	5 days	Diabetes mellitus
4	W ♀ 70	7 days	Abscess	5 days	No autopsy

The first patient was being unsuccessfully treated for Addison's disease when his symptoms of appendicitis began. His blood pressure, already low, fell further before operation and continued to drop after operation despite vigorous treatment. Patients 2 and 3 had severe diabetes mellitus which was difficult to control. Postmortem examination in each instance failed to show any definite cause of death, leading us to conclude that the general debility of these patients, together with their diabetes, rendered them unable to withstand the local infection and paralytic ileus incident to their condition. The fourth patient was a frail old woman who had had a laparotomy with hysterectomy many years previously. Old dense adhesions were found when the abdomen was opened, and the ileum was torn in the process of removing the appendix and draining the abscess. The operative procedure was long, but at first the patient seemed to do well. A fecal fistula developed three days after operation, and signs of pneumonia were observed on the following day. There was no evidence of ileus or peritonitis. No postmortem examination was made. It can be reasonably argued that this patient died as a result of too much surgical treatment. On the other hand, had the patient been younger and stronger or had there not been the technical difficulty resulting from the earlier operation, death might not have occurred.

TABLE 9.—Group 9 (Death from Obscure Causes)

Case	Race, Sex, Age	Duration of Symptoms	Operative Diagnosis	Postop- erative Course, Days	Autopsy
1	W ♂ 48	24 hr.	Peritonitis	4	Healing pelvic peritonitis
2	W ♀ 49	4 days	Peritonitis	7	No autopsy
3	W ♀ 60	14 days	Abscess	6	No autopsy
4	C ♂ 26	5 days	Abscess	12	Healing peritonitis

The first patient was considered clinically to have had pneumonia following operation. This was not verified at postmortem examination, nor was anything

found to explain his death. The second patient was very obese. There was a persistent high fever after operation but no clinical evidence of peritonitis or ileus. She too was thought to have pneumonia. Post-mortem examination was not made. The third patient appeared to improve after operation, but four days later azotemia developed; the patient became comatose and died on the sixth postoperative day. The clinical record of this patient does not justify any conclusion as to the cause of death. The fourth patient was very ill on admission and was thought to have mechanical ileus. In addition to appendectomy, an ileostomy was performed. The patient improved considerably for one week and then began to bleed profusely from the ileostomy wound. The bleeding decreased on removal of the enterostomy tube, but the patient became jaundiced after a severe transfusion reaction. Again he seemed to improve for a few days; then he died suddenly, without showing any new symptoms or signs. Postmortem examination did not furnish any explanation for his death. The typical lesions of mismatched transfusion were not found.

COMMENT

A number of recent papers have dealt with such technical matters as the choice of an anesthetic agent, the type of incision to be used, the manner of dealing with the appendical stump and the advantage of high ligation of the appendical vein. The principles of treatment are more important than the details. The anesthetic agent must be suited to the individual patient. A small muscle-splitting incision is adequate in most instances and will cause little trauma and spread of the infection, but we do not hesitate to use other types of incision when the need exists. Whether the stump of the appendix should be ligated and/or inverted depends on the operator's judgment in any given case. In our series of appendectomies there was no resultant abscess at the site of inversion, nor did a fecal fistula fail to heal spontaneously in a patient who survived. Only four of our patients had pyelphlebitis, and two of these had it before operation. More harm would result from attempts to secure high ligation of the appendical vein than from the ordinary procedure. The use of drains is open to question. We have employed drainage as a matter of routine when pus was present but have come to feel that the presence of drains may in some instances produce the adhesions which cause mechanical ileus. We are not prepared to say whether this danger is greater than that of the complications which might arise if drainage were not employed.

The most controversial subject which has arisen with regard to appendicitis is the so-called delayed or expectant treatment of perforative appendicitis. We feel unequivocally that this is poor treatment and that advocacy of this method has had an unfortunate effect on the general practitioner. In the first place, the most experienced surgeons are at times unable to determine with accuracy whether or not an acutely inflamed appendix has perforated. Granted that a patient has signs of peritonitis, it is not always possible to know the cause before operation. We are not alone in having discovered through a McBurney incision that peritonitis may be due to perforation of a peptic ulcer, to Meckel's diverticulum or to an infected diverticulum of the sigmoid flexure of the colon. In the past two years one of us has operated in three cases of primary pneumo-

coccic peritonitis, having made a preoperative diagnosis of perforative appendicitis. The correct diagnosis, made at operation, permitted treatment with specific serum and sulfapyridine, with prompt recovery. Rhodes³ kept a careful record of preoperative diagnoses made by a number of examiners and found that they were from 34 to 53 per cent incorrect with reference to the local pathologic condition, position of the appendix and extent of peritonitis. Selection of cases for delayed treatment on the basis of such predictions seems hazardous, to say the least.

Advocates of delayed treatment postulate that delay in operation affords a better opportunity to the body mechanism for defense against the infection. Doubtless the principle of physiologic rest for the affected tissues is as important here as in other parts of the body, and certainly handling and operative trauma should be minimized. We believe, however, that the first step in treatment should be elimination of the source of infection. This principle is not questioned in dealing with other perforative lesions of the gastrointestinal tract. Putting the gastrointestinal tract at rest with sedatives and restricting the diet, with the use of continuous gastric or duodenal drainage and intravenous fluids, are essential adjuncts to the treatment of appendicitis. In support of this statement we submit the figures in a series of cases observed in this hospital prior to 1931, before continuous suction and intravenous fluids were commonly used. In a series of eighty-five consecutive cases of perforative appendicitis treated in this hospital during the years 1928 to 1931 there were sixteen deaths, a mortality rate of 18.8 per cent. This is nearly twice that of our present series. The only real differences in treatment in the two series were the institution of suction and the administration of intravenous fluids in the cases making up the present series.

It has been argued that operation on an appendiceal abscess often spreads infection. In our series 283 patients with appendiceal abscess were subjected to immediate operation. In only two of them did spreading peritonitis cause death, and in one of these two the outcome was due to our failure to recognize and deal with the primary appendiceal abscess. In the other case it is not certain whether the spread of infection occurred before, during or after operation.

Another disadvantage of conservative treatment of perforative appendicitis is the fact that the appendix has not been removed when the patient recovers. It is often difficult to persuade a well person to have an appendectomy. This fact is shown by the reports on this method of treatment; a return to the hospital for appendectomy is secured at best in only 50 per cent of the patients. It is well known that further attacks of appendicitis will follow the first, and, in our experience, of forty-three patients in whom the appendix was not removed at the first operation, eight returned with a second attack of perforative appendicitis.

Finally, a comparison should be made of the mortality rates following the two methods of treatment. We are unable to do this satisfactorily, since no adequate basis for comparison can be established. The various advocates of the conservative method of treatment differ among themselves as to the selection of cases for that type of treatment. The mortality rates

reported by some⁴ vary from 8.1 per cent to almost 20 per cent for the series of cases selected for conservative treatment. The general average for the group is about 14 per cent. Patients entering the hospital in a moribund condition are often not included in the statistics of these reports, whereas all patients have been included in our series. The general mortality rate in our series is lower than the average rate for delayed treatment and is nearly as low as that of the most carefully selected series of cases. When we remember that many of the deaths in our series might have been prevented by better diagnosis and treatment, we feel justified in attempting to improve our mortality rate by more careful study and by better treatment of complications, rather than by adopting the method of delayed treatment.

SUMMARY

In a series of 1,317 consecutive cases of acute appendicitis, in all of which the condition was treated by immediate operation, perforation of the appendix with either abscess or peritonitis was found in 479. There were no deaths in the 838 cases in which perforation had not occurred. There were forty-eight deaths in the group of 479 cases, a mortality rate of 10 per cent. A study of the fatal cases leads us to conclude that some of these deaths should have been prevented by more careful diagnosis and better treatment of the post-operative complications. Even so, the mortality rate in our series is lower than the average reported for the delayed or expectant treatment of perforative appendicitis. For this reason and for the other reasons given we feel justified in continuing to perform immediate operation in the treatment of appendicitis.

Wolf-Children.—In his presidential address on this subject delivered before the Folk-Lore Society on February 21 . . . Dr. J. H. Hutton deals with the cases recorded from classical antiquity down to the present time of children having been reared by animals, especially wolves. The earliest record of a wolf-child which he has discovered in northern Europe is that reported by William Dilich in 1341 as occurring in Hesse. Two Lithuanian cases of wolf-children were described by Connor in his "History of Poland," published in 1698, since when no cases have been described in Europe. Many recent cases, however, have been reported from India, mostly from the United Provinces, and also from Central India, as well as from Africa. Wolves are not the only animals which have been said to have carried off and suckled children. In classical antiquity, Atalanta is stated to have been suckled by a bear and Cyrus by a bitch, while in recent times bear-children, jaguar- and leopard-children have been recorded in India, and lion-children and a baboon-child in Africa. It is a remarkable fact that no stories of the kind have been reported from the New World, where examples of wolf- and bear-children might have been expected from North America and jaguar- and puma-children from South America. Although it has been suggested that wolf-children are idiots who have wandered into the jungle and taken up their abode in the dens of wolves, this hypothesis is by no means universally applicable, notably in the case of the jaguar-child in the North Cachar Hills, India. Dr. Hutton comes to the conclusion that the evidence from India of wolf- and leopard-children and from Africa of a baboon-child seems to support the hypothesis that the belief is founded on observed facts.—*Nature* 146:58 (July 13) 1940.

TREATMENT OF APPENDICAL
PERITONITIS

WOOLFOLK BARROW, M.D.

LEXINGTON, KY.

AND

ALTON OCHSNER, M.D.

NEW ORLEANS

A critical review of 1,039 consecutive patients with acute appendicitis admitted to the Charity Hospital of Louisiana at New Orleans was undertaken in an endeavor to determine the most satisfactory method of treatment. In the entire group,¹ a large proportion of which came under our immediate care, there were fifty-six deaths, or a mortality rate of 5.3 per cent, a figure similar in magnitude to that obtained by others. A uniform request was sent to the record rooms of municipal hospitals in different parts of the United States. The results for a comparable period are shown in table 1.

In 860 (83 per cent) of the 1,039 cases the appendix was not ruptured at the time of entry. Prompt appendectomy was performed in every instance and was associated with seven deaths, or a mortality rate of 0.8 per cent. In one of the seven fatal cases the appendix was ruptured, with soiling of the peritoneal cavity during its removal. (In three other cases of acute appendicitis without perforation similar accidents occurred, without untoward sequelae.) Of the patients with appendicitis without perforation in this group, one in 123 died. Therapy of acute appendicitis without perforation will not be considered further.

One hundred and seventy-nine patients (17 per cent) had appendical peritonitis at the time of entry. Of this number forty-nine, or 27.3 per cent, died. One of every 3.6 patients with appendical peritonitis in this series died (chart 1).

Detailed analysis of these figures by age groups shows that the incidence of perforation with acute appendicitis is highest in childhood and in old age, although the incidence of the disease itself is highest in adolescence and early adult life, with 70 per cent of the patients between 10 and 30 years of age.

A reverse relationship obtains between the incidence and the case fatality rate; i. e., where the incidence is high, the mortality is low. In other words, the relationship between the percentage of patients with appendical peritonitis and the mortality in the various age groups is close, and the high mortality in the extremes of life is, in this series of patients, at least, more closely related to the high incidence of appendical peritonitis in that age group than to any other factor. The mortality rate of acute appendicitis without perforation in the various age groups is nearly the same, as is indeed that for patients with appendical peritonitis except in the group over 60 years of age, in which the mortality rate (table 2) rises sharply (eighteen patients and nine deaths).

Of the patients with acute appendicitis who died, 88 per cent had appendical peritonitis at the time of entry to the hospital. Of the total group, 17 per cent had appendical peritonitis at the time of entry.

In short, the problem of acute appendicitis in reality is the problem of prevention and treatment of appen-

dical peritonitis. By far the safest and surest measure to prevent appendical peritonitis is prompt removal of the acutely inflamed appendix before perforation has occurred. In our opinion there is no conservative treatment of acute appendicitis without perforation.

In this series, as elsewhere, the most important factor in the production of appendical peritonitis and death in the patient with acute appendicitis has been delay in instituting treatment. Seventy-four per cent of the patients with appendical peritonitis and 54 per cent of the patients who died waited more than two days after the onset of their symptoms before coming to the hospital. Although exact information is not available in this group of patients to determine the effect of catharsis on the incidence of appendical perforation and the mortality, our experience has been similar to that of Haggard,² Bower³ and others.

Of the 179 patients with appendical peritonitis, four died within so short a time that after admission to the hospital (less than twelve hours) that they will not be considered in the analysis except in computation of the mortality rate. All four were in shock at the time of entry. Three were not operated on. The fourth patient was unconscious and it was thought that she might have had a ruptured ectopic pregnancy. This patient died shortly after laparotomy, which showed generalized peritonitis of appendical origin. Three female patients who had generalized abdominal pain and tenderness associated with extremely rapid sedimentation rates were treated for pelvic inflammatory dis-

ease in the gynecologic service by hot douches, nourishing diet and enemas for distention. Although autopsy showed each of them to have appendical peritonitis, their cases teach little about treatment and will not be considered further except in computing the mortality rate. A girl aged 4 years was treated in the medical ward for gastro-enteritis for four days. Autopsy showed generalized peritonitis of appendical origin. A woman of 67 was treated in the medical ward with the diagnosis of cholecystitis. Autopsy revealed appendical peritonitis. A third patient, in the urologic service, was examined for a perinephric abscess. The patient died a few days after the removal of the perforated appendix through the exploratory lumbar incision.

From the surgical Services of the Charity Hospital of Louisiana at New Orleans and the Lexington Clinic.

Read before the Section on Surgery, General and Abdominal, at the Ninety-First Annual Session of the American Medical Association, June 12, 1940.

1. Ochsner, Alton: Postoperative Treatment, *South. M. J.* 29: 53 (Jan.) 1936.

2. Haggard, W. D.: Appendicitis: Analysis of 3,344 Cases, with Remarks on Delayed Operation in Delayed Appendicitis, *Am. J. Surg.* 28: 71 (April) 1935.

3. Bower, J. O.: Report of State Society Committee on Appendicitis Mortality, *Pennsylvania M. J.* 38: 257 (Jan.) 1935.

Indeed, incorrect diagnosis in cases of appendical peritonitis has been associated with the gravest prognosis. This was particularly true when enemas or catharsis had been used to relieve distention. A satisfactory prognosis cannot be expected without correct diagnosis and correct treatment. Except for determining the gross mortality rate in a statistical analysis, inclusion of such patients to determine proper methods of treat-

Chart 1.—Mortality of acute appendicitis. The column at the left represents the mortality percentage for the entire group, the column at the right for the group with appendical peritonitis.

ment would, in our opinion, confuse rather than clarify the results. Of the 169 patients with appendical peritonitis remaining, appendectomy was performed on ninety-four (55.9 per cent) as a primary procedure. Of these, thirty died, a mortality rate of 32 per cent. Seventy-five were treated by conservative methods (which included exploratory laparotomy without appendectomy and incision of residual abscesses as indicated), with nine deaths, or an indicated mortality rate of 12.6 per cent. Of fifteen patients with appendical peritonitis entering the hospital within twenty-four hours after the onset of their symptoms, twelve were treated by prompt appendectomy with two deaths; three were treated by conservative measures with two deaths (chart 2). Of ninety-two patients with appendical peritonitis entering the hospital from twenty-four to seventy-two hours after the onset of their symptoms, sixty-one were treated by immediate operation with fifteen deaths. Thirty-one were treated conservatively with five deaths (chart 3). Of sixty-two patients with appendical peritonitis whose symptoms were of more than three days' duration at the time of entry to the hospital, forty-one were subjected to immediate appendectomy, with three deaths; twenty-one were treated by prompt appendectomy with ten deaths (chart 4). We believe, however, that such figures fail to express accurately the entire situation, for we are convinced that operative intervention is the treatment of choice for certain patients with suspected appendical peritonitis.

In the first place, when the diagnosis of appendical peritonitis cannot be established with reasonable certainty, we agree with Gray and MacKenzie⁴ and others⁵ that, by and large, less harm is done by incision through the abdominal wall of the patient with appendical peritonitis than by omission of exploratory laparotomy in the presence of intestinal obstruction or a small, slowly leaking, perforated peptic ulcer.

We have also long been convinced that even if the abdominal wall is open it is wiser not to remove the appendix in cases of appendical peritonitis if adhesions must be broken down in its removal. This is particularly true, in our opinion, if the process is well walled off. During exploratory laparotomy in such cases appendectomy is done only if the appendix lies immediately beneath the incision and is not adherent to surrounding structures or there is a gross perforation at the base of the appendix through which intestinal contents continue to leak. With appendical peritonitis,

as with other conditions, the ultimate outcome depends on the outcome of the conflict between the patient's infection and his defensive powers to overcome it. In our opinion, when exploratory laparotomy reveals an open perforation through which fecal material continues to discharge, appendectomy aids the defense of the body by preventing further peritoneal soiling, but when the perforation and the appendix have been sealed off by omentum and surrounding intestine removal of the appendix, by breaking down the already established defensive measures of the body, may do more harm than good.

Again, if there is any doubt about perforation we advise exploratory laparotomy, for we feel that the damage done by exploratory laparotomy, with or without appendectomy, to the patient with appendical peritonitis is far less than that incurred by allowing an unruptured appendix to go on to perforation. The majority of patients with generalized peritonitis of appendical origin exhibit generalized abdominal pain and tenderness, absence of peristalsis on auscultation of the abdomen, rebound tenderness referred to the point of palpation of the left side of the abdomen, tenderness on both sides on rectal or vaginal examination and distention. (Of these, absence of peristalsis and abdominal distention are, in our experience, the most reliable.) In some patients with appendical peritonitis, however, particularly after localization has begun, one or more of these may be absent and the diagnosis of appendical peritonitis may be extremely difficult to make except by exploratory laparotomy. The converse may occasionally be true, for a patient whose appendix has not ruptured may present signs and symptoms suggestive of appendical peritonitis. This has been observed particularly of patients entering the hospital within twenty-four hours after the onset of their disease, and we have come to feel that the patient with acute appendicitis who enters the hospital within twenty-four hours of the onset is better treated by exploratory laparotomy and, almost without exception, removal of the appendix, regardless of the presence or absence of the clinical signs of perforation and generalized peritonitis. Perforation of the acutely inflamed appendix of a patient entering the hospital within twenty-four hours of the onset of the disease was found in only 4 per cent of the patients seen.

In those rare patients with acute appendicitis in whom distention and generalized abdominal tenderness develop within twenty-four hours, the symptoms in our experience have been due more frequently to peritoneal exudate and vigorous catharsis

than to gross perforation of the appendix. Another reason for urging appendectomy for these patients is the fact that if the appendix becomes ruptured within twenty-four hours the peritoneal cavity has had little time to prepare for such gross contamination and is poorly prepared to localize the infection. Operation in these circumstances usually shows an open per-

Chart 2.—Data on patients with appendical peritonitis seen within twenty-four hours of the onset. The column at the left represents those given conservative treatment, the column at the right those treated by immediate operation.

4. Gray, H. K., and MacKenzie, W. C.: Acute Appendicitis: Analysis of Results of Both Operative and Nonoperative Treatment in 674 Consecutive Cases, *S. Clin. North America* 17: 971 (Aug.) 1937.

foration which continues to discharge fecal material into the abdominal cavity, in contradistinction to those occurring from seventy-two to ninety-six hours after the onset of symptoms, which are usually largely sealed by omentum or surrounding intestine. Among the small group of fifteen patients who had

in six died when treated conservatively (chart 3). Such a statement of mortality, however, may be misleading, because for patients seen within four hours of the time of perforation, when the exact time of perforation can be established, appendectomy may well be the procedure of choice. Performed on patients with very recent perforation, in our experience, appendectomy has usually been followed by recovery.

Of sixty-two patients with appendical peritonitis whose symptoms were of more than three days' duration at the time of entry to the hospital, forty-one were treated conservatively with three deaths (one in fourteen). Twenty-one patients (chart 4) were subjected to prompt appendectomy with ten deaths (one in two).

We agree with Bancroft⁶ that it is a grave error to believe that just because a patient is not operated on he is being treated conservatively. Certain definite procedures based on the disturbance of physiologic function, which constantly occurs in patients with this disease,³ must be carried out if best results are to be expected. Although these measures have been detailed time and again¹ they will be briefly outlined here. The patient must be kept quietly in bed, so that localizing processes are minimally disturbed, a task which may be difficult with children. Too vigorous manipulation or examination may be disastrous. Elevation of the head of the bed will favor localization of secondary abscesses, if any, in the pelvis, where they can be detected and drained easily, rather than in the subphrenic space, where detection and treatment are more difficult.¹ Absolutely nothing by mouth should be given, in order to put the gastrointestinal system at complete functional rest. Distention is minimized by inhalation of concentrated oxygen⁷ and constant gastric suction of

acute appendicitis and perforation occurring within twenty-four hours of the onset of their disease, twelve were treated by prompt appendectomy, with two deaths; one of those who died was a boy aged 9 years and the other a woman of 73. Of three patients treated conservatively, two died (chart 2).

Of the patients entering the hospital between twenty-four and seventy-two hours after the onset of their disease, one in four died when treated by operation; one

the type advocated by Wangenstein. Of even greater value in decompressing the small bowel¹ is the double tube suggested by Miller and Abbott. The adynamic ileus accompanying the peritoneal infection can be combated satisfactorily by its use together with continuous suction. Intra gastric suction is also used to prevent the accumulation of fluid in a poorly functioning gastrointestinal tract. For the same reasons no food, solid or liquid, is allowed by mouth until gastrointestinal function has become reestablished as evidenced by detection of peristaltic sounds on auscultation of the abdomen. Morphine sulfate at regular intervals, usually one-sixth grain (0.01 Gm.) every three hours, unless the respirations are fewer than 14 per minute, both by its tonic action on the intestine⁸ and by its sedative action on the patient, has been found helpful. The fluid and salt balance of the patient is maintained by intravenous infusions twice daily. The administration of adrenal cortex extract is of inestimable value in combating the toxemia and aiding in maintenance of electrolyte balance. If nutrition by mouth must be withheld for a protracted period, multiple small transfusions help to combat anemia and hypoproteinemia. Sulfanilamide as an 0.8 per cent subcutaneous infusion was not used for these patients, but recently we have come to believe it to be of value in the treatment of appendical peritonitis.

An equally important part of the conservative treatment of appendical peritonitis is constant search for and appropriate treatment of secondary intraperitoneal abscesses. (Pylephlebitis and intrahepatic abscess will not be considered.) These will be considered in the inverse order of frequency.

The least frequent secondary intraperitoneal abscess is found in the subphrenic space. It may follow the original infection quickly or only after a prolonged interval. It is probable that infection in the subphrenic space without abscess formation is not infrequent and that it subsides spontaneously. There was one patient in this series of 1,039 who had a subphrenic abscess necessitating drainage. This patient recovered after a prolonged stay in the hospital. In two cases abscesses of the subphrenic space were found at autopsy.

Abscesses between the liver and the transverse colon are difficult to detect. In addition to the constitutional symptoms of continued sepsis, a mass in this region may be palpable. Incision is sometimes necessary; a short oblique subcostal incision is sufficient, but it is our impression that the great majority of subhepatic abscesses will subside spontaneously.

Chart 4.—Data on patients with appendical peritonitis seen more than seventy-two hours after the onset. The column at the right represents those treated conservatively, the column at the left those treated by immediate operation.

the type advocated by Wangenstein. Of even greater value in decompressing the small bowel¹ is the double tube suggested by Miller and Abbott. The adynamic ileus accompanying the peritoneal infection can be combated satisfactorily by its use together with continuous suction. Intra gastric suction is also used to prevent the accumulation of fluid in a poorly functioning gastrointestinal tract. Secondary abscesses in the left iliac fossa, as has been pointed out by one of us, are seen only in those patients with a shallow cul-de-sac, particularly children. Drainage through the left side of the abdominal wall is rarely necessary, for drainage of the associated cul-de-sac infection is usually sufficient for both.

Secondary infection in the cul-de-sac is, in our opinion, an almost constant companion to generalized peritonitis of appendical origin. Not a few such instances go on to abscess formation, but in many patients the induration and pain felt on rectal examination will subside spontaneously. Besides the constitutional signs and symptoms of continued sepsis, the patient with an abscess of the cul-de-sac has a loss of tone of the rectal sphincter as well as a boggy, fluctuant mass palpable on rectal examination. In the male patient, retention of urine may be the first symptom of an abscess of the cul-de-sac. Drainage through the rectum preceded by catheterization of the bladder and aspiration of the abscess has been satisfactory. An abscess in the right iliac fossa can be almost always palpated. In some instances such an abscess may attain tremendous size and yet give the patient no discomfort, either local or constitutional. In other instances a relatively small abscess in the right iliac fossa may be associated with severe systemic toxemia and demand drainage. Our experience has been similar to that of Lehman and Parker,⁹ who advise delay in operation until intervention is forced by a rising pulse and increasing fever, not only because the majority of such abscesses will resolve spontaneously but because a rather large mass in this region may be composed of indurated and inflamed mesentery and omentum and adherent loops of bowel with but little purulent material. When drainage has been necessary the McBurney incision and the extraperitoneal approach have been used.

SUMMARY AND CONCLUSIONS

In 860 of a series of 1,039 patients with acute appendicitis the disease was confined to the appendix; in 179 it had extended to the general peritoneal cavity.

The mortality among patients in whom the disease was confined to the appendix was 0.8 per cent; among those with appendical peritonitis it was 27.3 per cent.

Of fifteen patients with appendical peritonitis seen within twenty-four hours of the onset of symptoms, twelve were treated by prompt appendectomy with three deaths, and three by conservative measures with two deaths.

Of ninety-two patients with appendical peritonitis who entered the hospital from twenty-four to seventy-two hours after the onset of symptoms, sixty-one were treated by immediate operation with fifteen deaths; thirty-one were treated conservatively with five deaths.

Of sixty-two patients with appendical peritonitis with symptoms of more than three days' duration, twenty-one were subjected to immediate appendectomy with ten deaths and forty-one were treated conservatively with three deaths.

We feel that exploratory laparotomy is a wiser procedure than conservative measures in cases in which the diagnosis of acute appendicitis cannot be established with reasonable certainty or there is any doubt about perforation of the inflamed appendix and also for those seen within twenty-four hours of the onset of symptoms, although these factors are not subject to statistical proof on the basis of the material at hand.

190 North Upper Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. MILLER, FELL, BROCK AND TODD,
DRs. STAFFORD AND SPRONG AND DRs. BARROW
AND OCHSNER

DR. ALTON OCHSNER, New Orleans: The perennial question of the treatment of appendicitis has come up. There is this controversy concerning the treatment of appendical peritonitis but there is no controversy concerning the treatment of appendicitis per se. Even most ardent advocates of the conservative treatment of appendical peritonitis have emphasized the importance of immediate operation in uncomplicated appendicitis. Fortunately this morning no one has used the term "conservative treatment of appendicitis." The conservative treatment is limited to the treatment of appendical peritonitis. The statistics of Drs. Stafford and Sprong certainly are splendid, and one cannot deny the good results that they obtained. In Louisiana we feel that we have a somewhat different problem possibly from that which they have in Baltimore. Many of our patients come long distances from the bayous in southwestern Louisiana and practically all have had catharsis. Rupture is therefore usually present. The conservative treatment of appendical peritonitis is extremely difficult and the man who does occasional surgery will do far better by operating on these patients immediately irrespective of the time they are seen. We are convinced too that if there is any question about the advisability of operation or any question about the localization of the process the patient should be operated on. It is far better to operate on the patient unnecessarily and leave the abscess alone, back out, although it takes a great deal of courage to do it, than to overlook the possibility of a spreading infection. We are convinced that there are patients with a localizing disease, not a spreading peritonitis (every patient with a spreading peritonitis, unless moribund, should be operated on), who are better treated conservatively than operated on immediately. The difficulty is in the diagnosis. There is nothing that requires more surgical skill and judgment in distinguishing between these two groups of cases. If there is a definite localization as compared with a generalized tenderness, we believe that the case should be treated conservatively. These patients require a great deal more care subsequently. The incidence of intraperitoneal abscess is greater. Dr. Barrow has emphasized the importance of looking for these abscesses in particular locations. They are not difficult to diagnose if one will think of their possible occurrence. These patients should have rectal examinations done every other day at least, and many of the infections will subside spontaneously; but once the abscess has developed, it must be drained.

DR. E. H. FELL, Chicago: It has been of interest to note how much the papers have been similar in thought. However, Dr. Miller and his associates felt very definitely that all appendical abscesses should be treated conservatively and in that group which was treated conservatively only 2.5 per cent mortality occurred. I differ with Drs. Stafford and Sprong, and in their group which were operated on they had a mortality of 7 per cent. All patients with spreading peritonitis should be operated on and, I believe, should receive a very careful preoperative preparation. I do not take them from the examining room up to the operating room; their fluids should be balanced and blood given when needed. These important parts of the treatment of peritonitis are the preoperative and postoperative maintenance of fluids, proteins and electrolytic balances. In amplification of what Dr. Miller and his co-workers have said, I wish to call attention to four points: 1. Occasionally a definite palpable acutely tender mass may be present in the right lower quadrant during the early hours of an attack before a perforation has occurred, which is due to the omentum wrapping itself about the acutely inflamed appendix. Under these circumstances it would be unwise to follow the general rule as to conservation, and I believe that immediate operation is definitely indicated. 2. At times the clinical picture of an appendical abscess may be closely simulated by something which demands immediate surgery. I refer particularly to an atypical intussusception which has been present for some time. 3. Not every case of spreading or general peri-

9. Lehman, E. C., and Parker, W. H.: The Treatment of Intraperitoneal Abscess Arising from Appendicitis, *Ann. Surg.* 108: 833 (Nov.) 1938.

tonitis which apparently is due to a ruptured appendix is necessarily of appendical origin and therefore surgical intervention may occasionally be carried out when a conservative course would have been the wise policy. I refer to hematogenous peritonitis. 4. The patients in group 2 who have returned for appendectomy during the quiet interval, that is three months after the disappearance of a palpable mass, have shown at operation a variable pathologic type. Most times there have been a few adhesions between the appendix and the adjacent structures. Occasionally the appendix is embedded in a dense mass of adhesions and is difficult to remove. At times a small sterile abscess remains. The point I wish to make is this: In my experience, no matter how extensive is the pathologic condition, the operation can be carried out safely at this time without a mortality.

DR. HARVEY B. STONE, Baltimore: There has come to my attention, as one who frequently has to examine young surgeons for the American Board of Surgery, a keen recognition of the chaotic state of opinion as regards the handling of certain phases of appendicitis and its complications. Dr. Ochsner in his discussion has done well to point out that the controversy does not concern the handling of appendicitis *per se*, that there is no division of opinion as to the method in which simple acute appendicitis should be handled; we are all agreed that the only safe way to deal with that condition is by immediate operation. The variations in points of view arise when further complications of the original appendicitis have taken place, and particularly in those two groups of cases in which abscess has formed or in which a spreading peritonitis of varying degrees of intensity has developed. Perhaps the best discussion that one can make is to give his own point of view. I would agree with the paper of Dr. Miller and his co-workers almost in toto except for one point. They say that appendix abscess should not be operated on. If they would modify that by saying that appendicitis with abscess formation need not necessarily be operated on immediately, I would be willing to agree. I cannot feel that full obligation has been carried out to the patient in permitting him to go home without some certain knowledge that he will return or, better still, removal of his affected appendix before he is permitted to leave the hospital. The qualifications that Dr. Ochsner has placed about his advocacy of deferred surgical treatment of certain forms of acute appendicitis are very necessary, but it does not remove the basic objection to that form of treatment. He is careful to say that the postponement of operation is only a part of the treatment, that the rehabilitative measures which accompany the delay are fully as important a part of the treatment. I would like to submit the question as to whether the advantage which the patient obtains under this method of treatment is not due entirely to the rehabilitative measures and not to the delay. I cannot believe that this great concern to avoid intervention with a diseased appendix is justified in view of his apparent willingness to leave such a diseased appendix continuing in the abdomen. It seems to me that the basic principle of treatment of advanced disease of the appendix is the removal of the diseased organ and that the employment of the rehabilitative measures is important accessory treatment but does not get to the base of the trouble.

DR. JOHN S. HORSLEY JR., Richmond, Va.: I particularly want to endorse what Drs. Stafford and Sprong said and what Dr. Harvey Stone emphasized in his discussion. Of the appendectomies done as the main procedure at our hospital in Richmond, Va., from Jan. 1, 1931, to June 1, 1940, there were 706 cases of acute appendicitis with five deaths and none of those were due to peritonitis, a mortality of 0.71 per cent. There were 133 cases of acute appendicitis with peritonitis with three deaths, a mortality of 2.26 per cent. There were 258 cases of subacute and chronic appendicitis with no deaths. There was one case of carcinoma of the appendix. A total of 1,098 consecutive cases were done mainly for appendicitis with eight deaths, only one of which was due to peritonitis, and that was an abscess case, a total mortality of 0.7 per cent. With regard to acute appendicitis, ruptured and unruptured, there were 706 cases of the acute form with five deaths, 0.7 per cent mortality.

There were ninety-one cases of acute perforated appendicitis classified as abscessed and localized peritonitis with one death, and that was due to a spreading peritonitis, a mortality of 1.1 per cent. There were forty-two cases of generalized spreading peritonitis with two deaths, a mortality of 4.7 per cent. In the spreading peritonitis group the first patient had 2 feet of gangrenous bowel at the time of operation which needed resection, and the second patient in this group died four weeks after operation from pulmonary embolism. These operations have been done by three operators, three Horsleys, father and two sons, in one hospital and have been followed carefully and accurately. Based on these statistics we have come to a five point program which summarizes our ideas about the treatment of acute appendicitis, both ruptured and unruptured: 1. Immediate operation as soon as the diagnosis is made, no matter what the stage of the disease, whether abscess, general peritonitis or unruptured. 2. A small McBurney incision, with gentle handling of the tissues, and always removal of the appendix. In this group of 1,098 cases the appendix was removed in every instance at the original operation. 3. Use of suction apparatus instead of sponging to remove any fluid in those that have had a perforation. 4. Physiologic rest of the affected colon by avoiding proctoclysis and giving intravenously dextrose in Ringer's solution, using a Jutte or Abbott tube for decompression of the stomach and using a minimum of drainage. We have been using fewer and fewer drains until in the more recent months we have been closing many of the abdomens in cases of perforation without drainage except for the abdominal wall. 5. Simple treatment of the stump of the appendix, merely ligating the stump and bringing over a tag of peritoneum-covered fat to protect the stump from the drainage tube and any complicating adhesions.

DR. JOHN J. GILBRIDE, Philadelphia: It has been shown here that many conditions add to the mortality rate in acute appendicitis. An appendix that occupies an unusual position makes it very difficult sometimes to arrive at a correct diagnosis. In each of three cases in which the appendix was adherent to the urinary bladder the symptoms were largely those of vesical tenesmus, pain in the urinary bladder associated with pain and tenderness in the right lower quadrant. Pain and tenderness in the right lower quadrant led me to make a tentative diagnosis that the condition was one of appendicitis. Cystoscopic examination by skilled cystoscopists in each instance showed an area of hyperemia in the posterior superior wall of the bladder. The size of that area varied from 0.5 to 1 cm. The appendix was removed at operation and it was found to be adherent to the urinary bladder. It had not perforated into the bladder.

DR. EDWIN M. MILLER, Chicago: The greatest thing in surgery, as I see it, is surgical judgment. I would hesitate to question the surgical judgment of men like Dr. Harvey Stone, Dr. Ochsner, Dr. Stafford or Dr. Horsley but with some of the statements they have made we cannot agree. We wish to emphasize strongly that for patients in what we call group 2 with evidence of perforation, against which there has been established an adequate defense as demonstrable clinically by palpation of a definite local appendical mass (I don't say abscess) we believe that the conservative policy is by far the safest procedure, because we have plenty of evidence to show that in over 90 per cent of such patients careful observation, day after day, will show that the appendical mass will spontaneously subside and completely disappear; that only a few patients, less than 5 per cent in that group, will develop what is unquestionably a definite abscess that demands surgical drainage. I cannot agree with Dr. Horsley in his position when he says that not only should all such patients (*i. e.*, those with an appendical mass) be operated on but that the appendix must always be removed. In my opinion such a procedure is dangerous. Many times the pathologic condition is localized to the tip of the appendix, around which the abscess has developed. Two thirds or more of that appendix may lie entirely outside the walls of that localized mass, and to attempt to remove that appendix at the time of the acute process is only courting trouble.

HEALTH INFORMATION, PLEASE

HOMER N. CALVER

Secretary, American Museum of Health, Inc.

NEW YORK

A few weeks ago Amos and Andy were discussing the medical examination which Amos had just taken. They were agreed that a "catabolism" test did one a lot of good but were uncertain what it cured.

Few of us who are engaged in medicine or public health realize how meaningless to others are the words we constantly use and how incomprehensible are the processes of thought which we habitually follow. The bewilderment of the financier over a medical report, however, is similar to our bewilderment in a maze of figures. For instance, the following excerpt from a report to the stockholders of the ABC Company gives little reward for our efforts to decipher it from the small type in which it is printed:

To provide for the accounting adjustments above described all the corporate surpluses, both earned and capital, of ABC Company as of January 1, 1939, in the amount of approximately \$75,500,000, and the then existing reserve against certain investments, amounting to approximately \$6,500,000, will first be used, and then the new additional capital surplus created by the reduction in the stated value of the common stock, amounting approximately to \$134,700,000, will be utilized to the extent necessary.

Considerable knowledge of accounting practice is needed to elicit information from this sentence, even after careful study. It illustrates how wide the gulf is between the specialist and the layman. Further illustrations appear in Tonics and Sedatives every week.

The medical profession itself has been a principal contributor to this popular ignorance of medical matters. Unconsciously it has for the most part and until lately been bound by the tradition of the "medicine man," who practiced his mysteries to impress his tribe. I stress the word unconsciously because this picture of esoteric aloofness is not compatible with the concept of the true physician. Every doctor has been repeatedly reminded that his title means "teacher." Yet as far as I know medical schools never give him any training in how to teach. He is like an artilleryman with a magnificent supply of ammunition who has never been shown how to load, aim and fire a cannon. In his efforts to acquire these technics for himself it is not surprising if he is sometimes injured in a backfire.

This reluctance of the medical profession to take the public into its confidence has had at least three adverse effects on the profession itself. First, just as weeds will grow where crops are not planted, it has left the field open for the quack and the charlatan. To the layman without medical knowledge the jargon of the pseudoscientist is indistinguishable from the learned discourse of the physician. "Catabolism" sounds just as impressive as metabolism. The doctor must learn to talk in terms the public cannot misunderstand or else teach the public to understand the terms he uses.

Second, a man who does not understand the necessity for medical service or who is not aware of the resources which medical science offers is not likely to seek medical care even when he can afford to pay for it. Other public

services based on science have met this problem with benefit to themselves. The telephone company does not talk to the public in terms of dynes and ohms. It says "Speak directly into the mouthpiece." "Hold the receiver close to the ear." "Answer the telephone promptly." With the dial telephone, it has even taught us to be switchboard operators. Increased familiarity with this utility promotes increased use. The same has been true of the automobile, the radio and the electric light. It can be true for medical service also. Many a physician already will tell you he has had increased demands for diphtheria immunizations after a public campaign for diphtheria prevention. Such results can be extended to cover the whole field of medical practice.

A third adversity which the profession must now face, partly as the result of its own negligence, is a flood of propaganda for new systems of medical care. Though better and more widespread health education may not have prevented this social development, the proposals themselves would be based on a greater appreciation of the realities if the proponents always knew what they were talking about. It is perhaps significant that government efforts to regulate the telephone monopoly have not made much progress.

To a considerable extent a program of health education is a public relations program for the medical profession and its allied workers. In a democracy such programs to be effective must reach a large proportion of the whole mass of people. They must be as intense and as far reaching as the preparations of a dictator for war. Indeed, mass health education is a necessary step in the totalitarian war against disease, which it is high time we began. One wonders whether in the next draft the physical condition of our young men will prove to be any better than it was last time. The mobilization of a whole population for a total war against disease and preventable death is not a small task. It must have greater breadth and depth than is represented by the present trickle of pamphlets, lectures, radio talks and motion pictures, however excellent these may be individually. The situation calls for a better integration of effort, more well trained leaders, a better understanding and use of available technics and a large increase in financial support.

The museum of health is conceived to be an important instrument in this necessary program of preparedness and engagement. The program calls for not just one museum, such as the American Museum of Health which you can see in the initial and more obvious phases of its operation at the New York World's Fair, or such as the Cleveland Museum of Health and Hygiene, which will open its doors to the public this year, but for many museums spread throughout the country like a vast division of heavy tanks, each with its own board of directors, employees and funds, and a program devised to meet the dispositions of the enemy in its territory. In each locality the medical profession must take a leading part in the creations of such museums, as it has in New York and Cleveland.

The American Museum of Health in New York was the result of some ten years of planning. It is now in its second year of operation. Its sole activity thus far has been to prepare and present a popular exhibit on medicine and public health at the New York World's Fair. It has plans for a large number of other activities

in line with its objectives as an institutional headquarters for mass education in health. It has already collaborated and hopes to extend its collaboration with national and local professional, voluntary and official health and medical organizations and a number of other agencies. It has adhered to the principle that showmanship and science are of equal importance, and that failure will result if either is made subservient to the other.

THE VISITOR REACTION STUDY AND SUPPLEMENTAL INVESTIGATIONS

A serious and justifiable criticism of health exhibits as well as all health education activities is that the good they do is unknown. The health educator has not in general attempted to demonstrate that his work has saved lives, as the laboratory man has shown that his service has prevented disease. Results have been reported in terms of subjective opinion which were not supported with objective data. When the American Museum of Health embarked on its work, therefore, it at once set up plans for a study of its own operation and of the public who were its patrons.¹ This plan was organized as a "Visitor Reaction Study," which operated chiefly at the New York World's Fair. Similar supplemental studies are being carried on this year in both the New York and the San Francisco fairs.

The Visitor Reaction Study included a dozen or more test procedures devised by Dr. Mayhew Derryberry² and his associates and applied to more than 50,000 visitors. No one person was given all the tests, and no one test was given to everybody. In each case the test was used with a sufficiently large group so that the results would be statistically significant. Analysis of this enormous volume of data will not be complete until this fall. Some tentative observations can be made now, however, on the basis of some analyses completed or in progress. It is to be emphasized that these observations are necessarily tentative and subject to amendment when the study of the data is completed.

From the opening day, when 60,000 visitors were clocked in, it was obvious that the exhibit would be a major attraction. When the fair closed on a rainy Hallowe'en, the Medicine and Public Health Building had rolled up a total attendance of more than 7,500,000. Of this it is estimated that 5,542,000 visited the Hall of Man and 4,947,000 visited the Hall of Medical Science. An analysis of fifty-two exhibit units in the Hall of Man showed that the number of visitors who stopped to look at the four most popular exhibits were, in round figures, Transparent Man, 3,340,000; Embryo Panel, 2,302,000; First Year of Life, 2,161,000; Maze of Superstition, 2,115,000. Least popular were four panels representing the organs of smell, the mechanics of hearing, the organs of taste and the mechanics of vision. These exhibits had only from 123,000 to 189,000 apiece. The number of visitors to the twenty-five exhibits in the Hall of Medical Science showed that the most popular were Anesthesia, 1,143,000; Carrel-Lindbergh Culture of Organs, 1,397,000; Education of the Blind, 1,369,000; Cancer, 1,289,000. The least popular were Mental Hygiene, 439,000; Safeguarding Medical Products, 361,000; Social Hygiene, 351,000; Industrial Sanitation, 243,000.

Our studies, however, were not confined to a mere counting of visitors. The exhibits were rated according to choice by approximately 20,000 visitors, and these ratings are being compared with similar ratings by three hundred experts. Comments were solicited from time to time and a record was kept of *unsolicited* comments made to the attendants. Tests were made which indicated the general level of health information of the public, and these data are being analyzed with respect to age, sex and other factors. Experiments were undertaken to determine the reading difficulty of legends. In many instances it was extraordinarily difficult to write a legend which was scientifically satisfactory as well as popularly understandable.

In the course of the study an attempt was made to ascertain what subjects the public would like to see treated in exhibits. Six subjects which were not covered and about which there had been frequent inquiry were submitted to some 20,000 individuals with this question: "Would you be interested in seeing an exhibit on the following subjects? Please check." The number checking these six topics were: Birth Control, 54 per cent; Need for Periodic Health Examinations, 46 per cent; Hospital Insurance, 39 per cent; Abortion, 33 per cent; Compulsory Health Insurance, 29 per cent; Arthritis, 26 per cent.

As might be expected, the age of the visitor determined to a striking extent his interest. As age increased there was a marked increase in the percentage of persons interested in periodic health examinations and arthritis and a less marked but nevertheless appreciable increase in the percentage interested in hospital and compulsory health insurance. Excepting in the 21 to 30 age group, age is inversely correlated with the proportion of individuals interested in exhibits on birth control and abortion. There were also interesting sex differences. More females than males were interested in arthritis, and this disparity in interest increased with age. More males than females were interested in compulsory health insurance, and this difference in interest remained approximately constant as age increased. In the under 21 age group the percentage of females interested in birth control and abortion was significantly higher than the male, but this sex difference was not apparent in the older age groups. Since no data are available on the actual age distribution of visitors to the Medicine and Public Health Building, deductions should be made with caution from the total percentage figures.

At the same time, visitors were given an opportunity to suggest other subjects. The answers to approximately 1,600 suggestions have been grouped into ten categories. The category which had to do with diseases exceeded all others by two to one, but it will interest this group to know that the second largest category was that which included the various replies dealing with some aspect of medical training and organized medical service.

The question has been raised whether or not health exhibits contribute to hypochondria. An effort to answer this question was made through the Gallup poll technic. Trained interviewers asked 1,000 individuals "Has looking at these exhibits suggested to you that you might have some condition that needs correction?" Approximately 10 per cent replied in the affirmative. Some of them admitted that they were concerned about themselves before they saw the exhibits. Others indicated that they were sufficiently disturbed to consult

1. For this purpose the museum was fortunate in securing funds from the Carnegie Corporation of New York, the active collaboration of the U. S. Public Health Service, and material assistance from the New York World's Fair, the National Youth Administration, the Works Progress Administration and a large number of other organizations and individuals.

2. Senior Public Health Statistician, U. S. Public Health Service.

a physician—which might be classed as a desirable result. The final comparison of the data with the normal hypochondria rate—if there is such a thing—should prove interesting. In any event, no epidemic of hypochondriasis has since been reported.

With one exception no diagnostic procedures were included in the exhibits. This exception was the rapid chest x-ray survey conducted by the Queens County Medical Society. In this exhibit more than 11,000 paper roentgenograms were made. Readings of all these were done by specialists in this field designated by the county medical society. Negative results were reported directly to the patient with an appropriate word of caution, and positive readings were referred to the patient's family physician with a letter of explanation. Reports of the radiologists indicated that a little better than 3 per cent of the roentgenograms showed pulmonary tuberculosis which was probably active in the first, second or third stages.

One of the most important questions we set ourselves to answer was "What did the public learn from the exhibits?" Some 30,000 people were asked to fill out test blanks on each of which were twenty-five questions relating to health. Some of these questions were based on the exhibits and some were not. Some people answered the questions before they had seen the exhibits, and others answered them after they had seen the exhibits. Those who had seen an exhibit made significantly higher scores on the test questions relating to that exhibit than those who had not seen the exhibit, with the exception of one exhibit.

From the analysis of this material, we are accumulating a wealth of valuable corollary data and learning that some exhibit technics are ineffective. For instance, it would seem that certain types of statistical facts are not easily absorbed and may by their method of presentation give a wrong impression.

Some preliminary analyses indicate that the pneumonia exhibit failed to register the fact that rusty sputum is a symptom of pneumonia, and the cancer exhibit was not getting across the idea that surgery and x-rays were acceptable methods of treating cancer. In other words, we had abundant evidence that there were good ways and poor ways of telling our story. Things that seemed so clear to us in the words, pictures and charts were sometimes considerably less than clear to many people.

A report of the Visitor Reaction Study will be published this winter. Representing as it will a sampling of 7,500,000 people, it should be of enormous value to all who are engaged in health education or exhibit planning in any field.

Our experience already warrants several conclusions:

1. The people thirst for knowledge about themselves.
 2. It cannot be assumed that those who have this knowledge are able to give it to the public in a way it will understand. Study and elaboration of effective technics for imparting medical and health information through exhibits and otherwise are needed.
 3. It has been demonstrated that the museum of health is an effective instrument for mass education for health.
 4. It is a fair deduction from experience in other fields that increased popular knowledge of medical matters will result in increased use of medical service.
- The members of the American Medical Association have a great opportunity to benefit the public as well

as their profession if they will take the leadership in their communities in the development of museums of health which constantly test their health education programs objectively for results.

30 Rockefeller Plaza.

ABSTRACT OF DISCUSSION

DR. HARRISON S. MARTLAND, Newark, N. J.: I first met Mr. Calver at the time he was planning and organizing the New York World's Fair medical exhibits. While directing these public health exhibits he has had a unique opportunity to demonstrate the popularity, value and necessity of permanent public health museums for lay education. Further evidence of the popularity of lay medical exhibits has been demonstrated this year in Essex County, N. J. The president of the county medical society at the time, Dr. Royal A. Schaaf, felt that lay education was a most important function of a county society. He said "Why not have a Medical Week." We did that. There were over forty exhibits covering such subjects as cancer, pneumonia, fractures, first aid, endocrinology, vitamins, pediatrics, obstetrics, allergy, hygiene, serums and antitoxins, instruments of precision as employed in medicine, blood transfusions and operating room technic. The exhibit on the value of autopsies was most unusual. Letters from leading Catholic, Jewish and Protestant clergymen were prominently displayed. These letters indicated that there were no religious objections to the properly performed autopsy and were read with great interest by the public. Medical motion pictures of general interest were continuously shown and special lectures for the laity were given. The speakers were prominent physicians from other parts of the country. The exhibits were in charge of nurses, technicians or interns, and all publicity as far as personal medical advertising was concerned was prevented. During the week in a community of about 900,000 the exhibit, which had been widely advertised in the newspapers and stores, drew over 40,000 people. On one day alone 13,500 attended the exhibits, and at one of the evening lectures more than 1,500 had to be turned away. We feel that two main objectives were attained: First, to demonstrate to the community that the county society is also an educational institution and not a selfish economic body. Second, to gain the good will of the public for organized medicine. Of course in an exhibit of this type there are many pitfalls, and diplomacy is necessary. At the end of the exhibit, however, we felt that the attempt was well worth while and would accomplish more than the many other efforts to combat quackery, cultism and unworkable social changes in the patient-doctor relationship. There is a real necessity for adequate permanent public health exhibits, and these may by education solve many of the public relation problems now besetting the medical profession.

MR. HOMER N. CALVER, New York: Dr. Martland's report of what they did in Essex County suggests what other county medical societies can do in this direction. I should like to emphasize that the situation calls for more than sporadic or temporary effort, as illustrated in a one week or two week exhibit. Disease doesn't attack one week or two weeks at a time. It is with us always, and we see the museum of health, as distinguished from the temporary exhibit, as an institution which will continuously wage war against ill health as the exhibit does temporarily. I should like to express our profound gratitude to some 300 to 400 leaders in the medical profession whose time-consuming effort made possible this show we now have. They met, I assure you, often and long, and without their guidance this project could never have been launched.

Relaxation.—The benefits to be gained from frequent periods of relaxation are by no means fully appreciated by the majority of people. To lie down for a few minutes after lunch and relax, even though we do not actually lose consciousness, will drop the blood pressure and pulse rate, remove the feeling of being rushed or harassed, and fit the individual for his afternoon's work to an extent considerably out of proportion to the time expended for the purpose.—Smiley, Dean Franklin, and Gould, Adrian Gordon: *A College Textbook of Hygiene*, New York, Macmillan Company, 1940.

THE MINIATURE X-RAY FILM IN THE "TOTAL SURVEY"

FREDERICK TICE, M.D.

President, Board of Directors, Municipal Tuberculosis Sanitarium
CHICAGO

The necessity for a "total x-ray survey" in certain areas of high mortality in Chicago has long been realized. By total survey is meant survey, in the district selected, of every man, woman and child, reaching toward an ideal though probably unobtainable objective of 100 per cent. The reasons for such an effort were compelling. In Chicago the tuberculosis problem, largely enclosed in the Negro (281.7 per hundred thousand mortality against 34.0 per hundred thousand mortality in the white population) is, to a certain extent, geographically circumscribed. In 1939 six predominantly Negro census districts, with 17.5 per cent of the population, accounted for 47.8 per cent of the tuberculosis deaths.

An x-ray project of the magnitude indicated was far beyond our means in terms of the standard film and the project, necessarily, was held in abeyance. Finally,

View box for miniature x-ray films.

with the advent of x-ray photography, practically initiated by Manoel De Abreu of Rio de Janeiro, introduced in this country by Lindberg and Potter, came the answer to our problem. In the work being reported here the photoroentgenographic unit developed by one of the equipment houses in collaboration with Potter, reported elsewhere by Potter and Douglas, was used throughout. The size of the film is 4 by 5 inches and the approximate cost of each film is 5 cents. In the perfection of this photoroentgenographic unit the Municipal Tuberculosis Sanitarium demonstrated its interest and cooperation by referral of the tuberculous and non-tuberculous cases necessary for the experiment.

For purposes of the total survey, the photoroentgenographic apparatus was installed in a mobile x-ray unit, already in our possession. This unit consists of standard x-ray equipment, complete with dressing rooms, ventilators and fans, mounted on a balloon-tired 2½ ton truck and supplied with 200 feet of cable for connection with the power outlets.

PROCEDURE AND ORGANIZATION

X-ray examination within easy walking distance was a prime objective. The prospects would not walk long distances. Neither, as we knew from experience, would

they or could they use the street cars. Owing to economic conditions prevalent in the areas to be surveyed, the carfare, involving rides for all the members of the family, was in itself prohibitory. It resolved itself therefore into a question of the mountain and Mahomet.

Laying out the work in accordance with this idea, Census District 35 (highest mortality area in the city) was surveyed and stations were so selected that the patients living farthest away would have to walk only a few blocks. Many lived in the same block, around the corner or across the street. The response to our request for free space and facilities was encouraging. Such organizations as the Y. M. C. A., other municipal clinics, welfare organizations, factories, even a police station, were approached and offered cooperation. The location first chosen was the Negro Y. M. C. A., situated in the heart of this area of high mortality.

Preceding the actual work at the Y there was, of course, the usual publicity and educational build-up. Employed and exploited to the full were such mediums as the local newspapers, posters, trailers in the local movie houses, radio talks and brisk liaison with such organizations as the medical society, insurance companies, funeral aid societies, the churches, welfare groups and others.

Contemporaneous with the campaign of education and publicity, ten field nurses were assigned to make an intensive house to house canvass of the one-half square mile immediately surrounding the Y. These nurses further enhanced the publicity, established a building record and family count, furnished assignments for x-ray examination and prosecuted the follow-up. The truck, at the first assignment, was in operation seven days a week, including Sunday, from 1 to 9 p. m. Daily attendance ran from a low of 100 to a high of 300. The entire family was urged to report at the unit and repetitive nurses' visits supplemented with form letters continued the stimulus. Starting April 15, 1940, 10,000 patients had been filmed by June 20, and this report was organized to include data of patients examined to June 18.

X-RAY INTERPRETATION

To avoid individualistic trends, the films were read by a committee of four head physicians, all especially experienced in x-ray interpretation. Opinion had to be unanimous on every diagnosed case. If one member of the committee disagreed, the case was classed as "suspect" and a 14 by 17 film ordered. In addition, all films showing suspicious or abnormal markings were classed as suspects and similarly followed up.

With regard to the technic of film examination, the hand glass, used at first, was found to be tiring to the eyes and unsatisfactory. Owing to the fact that the development was new, no view box for the 4 by 5 films was available. Urged by necessity, the Superintendent of Clinics designed a box which has given excellent results. The apparatus, shown in the accompanying illustration, is a double cone shaped box 22 inches long with a 4 inch magnifying glass at the anterior apex. A runner 30 inches long, capable of holding six miniatures, is part of the equipment. This runner is loaded by an assistant and the films are passed rapidly across the illuminated opening in the face of the posterior cone. The magnified image is about 8 by 10, is easy on the eyes and shows a fine differentiation of detail. For the convenience of the committee, the arrangement is mounted on a swivel base so that the viewing apparatus can be quickly rotated to each examiner in turn.

FORMS AND STATISTICS

The statistical material covering the primary examination is compiled on both sides of the small manila envelop used to hold the miniatures. The front of the envelop contains the identifying data, the back the diagnosis, classification and other items. Several other forms are used, including the housing record to show the number of residents per house or flat, assignment blanks, a form letter of notification to all negative cases and a form letter for reference of nontuberculous conditions. All diagnosed and suspected cases are fully charted in the usual way and subjected to clinic supervision. All plates read as tuberculous are sent immediately to the extramural collapse clinic for study concerning the possibility of ambulant pneumothorax. As a side issue and as a phase of social service work, patients showing cardiac or nontuberculous pulmonary conditions are referred to the indicated clinics.

RESULTS

Of the 10,000 cases in which x-ray films were made to June 18, 1940, 9,348 were fully analyzed and charted. Of these cases 8,942 were of Negroes, 340 of white persons, thirty-four of Mexicans and thirty-two of others. Table 1 furnishes the breakdown according to race and sex.

The principal highlight in this tabulation centers on the 351 cases of "reinfection type" tuberculosis discovered. To these may be added the forty-five cases read as suspects on the original miniature and diagnosed as tuberculous in later films. The addition of the forty-five cases raises the percentage of roentgenologically demon-

x-ray examination of the large "suspect reinfection" group will increase the disease incidence above the figures given.

The disease incidence of 5.29 per cent in the 340 white persons examined, against the 3.71 per cent in the 8,942 Negroes examined, is interesting from the

TABLE 2.—Negro Cases: Analysis by Age and Sex

Ages	Total X-Ray Examinations			Reinfection Cases

fact that the rates run counter to the usual concept. To all intents and purposes the white persons examined in the present survey live under the same sociologic, environmental and economic conditions as the Negroes. Are the rates, as quoted, merely accidental or do they adumbrate an actuality? The number of white persons in the 10,000 x-ray examinations is too small to justify any basis for conclusions. In the course of a year, with seventy or a hundred thousand total x-ray examinations, including possibly four or five thousand white persons, the figures in final analysis should throw some light on a highly debatable question, the relative disease incidence between Negroes and white persons in similar economic brackets.

WHITE RACE

Owing to limitations of space and paucity of material, the analytic tabulation for the 340 white persons is not submitted. One fact needs to be mentioned concerning the white persons in the fifteen years and over period: a total rate, "reinfection type," for both sexes of 6.8 per cent, 9.5 per cent for the males, 4.5 per cent for the females. The figure, particularly for the males, is high. Further investigation will doubtless reveal that many of these cases have been contacts to open tuberculosis and such an investigation also will show that the families live under extremely poor environmental conditions.

NEGRO RACE BY AGE AND SEX

Table 2 gives the data on the 331 Negroes diagnosed as tuberculous and furnishes analysis on the lines of age and sex. The original work sheet, too detailed for consideration here, carried the analysis through the 648 cases listed as roentgenologic suspects and the 7,963 cases listed as roentgenologically negative. Although altogether 8,942 Negroes were examined and data charted in a routine manner for each case, owing to reasons of space limitations only the 331 diagnosed cases are considered here.

TABLE 1.—Results by Race and Sex of 9,348 X-Ray Examinations

strable tuberculosis found from 3.75 per cent to 4.24 per cent. In comparison with mass surveys reported elsewhere, the percentage seemed rather high. It must be remembered, however, that the district surveyed represents the area of highest mortality in Chicago, 301.6 per hundred thousand. In such a district, surveyed in a routine manner, one may expect an unduly high morbidity in terms of demonstrable disease. As a matter of fact and with reference to both white and Negro, it may be presumed that follow-up and later

The high percentage of roentgenologically demonstrable tuberculosis, as shown in this table, for the age period 50 to 74 is significant. Presumably many or most of these cases were of the chronic, fibroid type and represent "fountains of infection." A tabulation dealing with the type of lesion as revealed by the x-rays

confirms this supposition. The tabulation is not given here but the summary shows a marked predominance of fibroid type lesions.

Referring again to table 2, crossing age against sex, taking the adolescents and early adult years, 15 to 29, the increased tuberculosis incidence in the Negro females corresponds roughly with the increased mortality for the period as revealed by the general tuberculosis death rate. Grouping the three periods shown in the table, the incidence for the males is 3.9 per cent against 4.9 per cent for the females. These figures represent an excess incidence for the females of 26 per cent, a ratio which holds for the mortality rate as revealed by the 1939 mortality tables for Chicago. The incidence rate for the children under 14 is also interesting, 0.6 per cent for the males, 1.0 per cent for the females, an average rate for both sexes of 0.8 per cent. This rate is significant. If continued at or about the level quoted, it will exercise an influence in outlining the future scope and purposes of the work.

In laying out the survey, the question arose as to whether children should be accepted for x-ray examination. Was x-ray examination of the children worth while? In a recent school survey comprising over 187,000 Chicago school children, the rate of case incidence under 14 years ran 0.72 per cent for the tuberculin positive children roentgenographed, 0.06 per cent for the total children tested. The rate for the Negro children was 1.01 per cent for the tuberculin positive children roentgenographed, 0.15 per cent for the total

children tested. On the basis of these figures we necessarily had to consider the economic advisability of roentgenographing the children. We decided, however, to follow the original idea and roentgenograph the entire family. Though the futility of child x-ray examination in general groups must be conceded, the results in this area of excessive mortality seem to justify the procedure. An incidence of close to 1 per cent is well worth the effort and expenditure and discloses sidelights of interest from two totally different angles. Such a rate in children, objectively shown by the miniatures, reveals both the density of evolutive infection in areas of high mortality and the superiority of total x-ray examination over the old screen method.

STAGE OF DISEASE AGAINST RACE AND SEX

That serious pulmonary disease in appreciable amount is found in children of the substandard neighborhoods is demonstrated in table 3. In analyzing the twenty-four cases found, 14 years and under, it will be seen that twelve, or 50 per cent of the cases, were moderately advanced.

Studying the table further, it is seen that stage of disease shows a more or less consistent distribution for all age periods. Of much more importance are the figures relative to minimal tuberculosis. In view of the fact that, of the 863 Negroes diagnosed tuberculous in our clinics during 1939, 12 per cent were minimal and 88 per cent advanced, the ratio of minimal cases found in the survey, 48 per cent, must be considered as extremely gratifying. Many of these early cases showed excellent indications for pneumothorax and were referred to the collapse therapy clinic. The financial saving to the community represented by the discovery and prompt treatment of such early cases is obvious.

TYPE OF LESION

Considerable difference of opinion exists as to the possibility of accurately typing lesions from the x-ray plates. The tabulation covering this point is too lengthy for inclusion. The totals, arranged according to the classification decided on by the interpretation committee, run as follows and are submitted for what they are

TABLE 4.—*Incidence of Primary Tuberculosis as Revealed by the Miniatures*

worth: Of the 351 cases diagnosed, 45 per cent were classed as infiltrative, 14.8 per cent as exudative, 11.9 per cent as ulcerative, 0.9 per cent as proliferative, 3.5 per cent as cavernous, 33.6 per cent as fibroid and 10.0 per cent unclassified. Some of the patients, of course, had more than one type of lesion. Needless to say, any such classification is merely tentative and empiric, and sound decision as to type of lesion will have to wait on clinical observation as the patients go through the clinics.

PRIMARY TUBERCULOSIS

The committee again found itself on debatable ground in attempting to outline a classification for primary tuberculosis. The classification finally decided on is given in table 4, and the results are shown both for all films read and for films diagnosed "reinfection type." The table is shown for what it is worth and without the exhaustive analysis which is carried on the work sheets. Details on this and many other points will be furnished in a bulletin to be published later.

In studying the tabulation it is seen that 37.0 per cent of cases diagnosed reinfection type showed visible primary, as against 14.8 per cent for all films read. The significance of this finding is a matter of speculative interest and further research along this line is indicated.

NONTUBERCULOUS PULMONARY CONDITIONS

Of the Negroes examined, 6.4 per cent showed cardiac conditions and 1.9 per cent showed nontuberculous respiratory conditions. The figures for the white persons were 4.7 per cent cardiac and 2.6 per cent nontuberculous respiratory.

THE FOLLOW-UP

Owing to the fact that the work is continuous, the follow-up of the "suspects" is necessarily incomplete. Of the 680 persons diagnosed as having suspect reinfection, 287 have already been reexamined with the 14 by 17 film and more are coming in each day. Of the 287 cases already examined forty-five, or 15.7 per cent, have been diagnosed as pulmonary tuberculosis, 108, or 37.6 per cent, have been diagnosed as negative, and 134, or 46.7 per cent, have continued as suspects. From present indications, follow-up of the suspects represents a productive field and this phase of the program will be further intensified as the survey continues.

SUMMARY AND CONCLUSIONS

In the two months survey, 9,348 persons were roentgenographed and classified, of whom 351 showed roentgenologic evidence of tuberculosis on the original miniatures. Of the 351 cases discovered 167, or 47.6 per cent, were minimal, 141, or 40.2 per cent, moderately advanced and forty-three, or 12.2 per cent, far advanced.

Contrary to the usual concepts and to the trends of the mortality tables, the 340 white persons roentgenographed showed a higher rate of incidence than the 8,942 Negroes.

Total survey, including all members of the family, was justified by the unusually high rate that was found in children.

Total survey through the medium of the miniature film and the mobile x-ray unit is at last an economic possibility and, in view of this new development, case-finding procedures will have to be revised.

The miniature film represents a new and efficient public health instrument destined probably to general acceptance by all communities with a serious tuberculosis problem.

Contrary to the opinion which seems to prevail for the moment in this country, I am convinced that future developments will lie in the direction of a still smaller and a still cheaper film, possibly the 35 mm. film as used by De Abreu of Rio de Janeiro. The technical difficulties involved are not insurmountable and the reduction in cost, reaching as low as a cent per film, constitutes a perennial inducement to further research.

EXPERIENCES WITH SURGICAL TREATMENT IN TEN CASES OF PATENT DUCTUS ARTERIOSUS

ROBERT E. GROSS, M.D.

BOSTON

The ductus arteriosus is a vessel which is essential for the fetal circulation but which ceases to be necessary after birth when expansion of the lungs allows more blood to flow through the enlarged pulmonary vascular bed. Having fulfilled its function in prenatal life the ductus normally becomes closed off following delivery of the child. Christie¹ found that 95 per cent of routine postmortem subjects at 12 weeks of age had a closed ductus and that 98.8 per cent of them at 1 year had this vessel obliterated. If the ductus arteriosus remains open during childhood or later life, the passage of blood through it (from the aorta to the pulmonary artery) forms an arterial leak which may assume considerable importance. If the ductus is small, the patient can indulge in reasonable activity and may have a normal life expectancy. If, however, the ductus is relatively large, physical work may be greatly limited and indeed death may follow by one of several mechanisms.

It is difficult to state how frequently the patent ductus arteriosus gives rise to significant pathologic change. A case in which death results from this abnormality is apt to be reported in the literature, whereas cases of the fistula without its major complications usually have little medical recognition as far as journalistic record is concerned. Although internists and cardiologists are cognizant of the fact that occasional patent ductus patients are 50 or 60 years old and in relatively good health, a collective survey of the medical literature would give a somewhat gloomy outlook for the individual who is beginning life with this abnormality. Abbott² has studied ninety-two fatal cases of patent ductus arteriosus in which there were no other cardiovascular abnormalities. In this group 43 per cent died of sudden or slow cardiac failure and 30 per cent died of subacute bacterial endocarditis or endarteritis of the pulmonary artery. The average age at death was 24 years. Bullock, Jones and Dolley³ placed the incidence of bacterial infection at an even higher level. Little attention has been given to the fact that children with a large shunt between the aorta and the pulmonary artery may have a deficient peripheral flow of blood and consequently a retarded physical development. There are now sufficient physiologic observations in this regard⁴ to show that delayed growth may be produced by persistence of the ductus.

To present accurate figures on the incidence of these various complications is impossible at the present time, because no one clinician or clinic has had sufficient experience to compute the prognosis. However, it is evident that subacute bacterial endarteritis, retarded

This study was supported by a grant from the Godfrey M. Hyams Trust.

physical growth and heart failure are frequent enough to warrant surgical attempts at closure of the ductus in selected cases with the hope of diminishing the incidence of these sequelae. In February 1939 Gross and Hubbard⁵ published a report of the first successful ligation (August 1938) of a patent ductus arteriosus. In March 1939 Gross⁶ described an operative approach for this procedure and listed four cases in which this had been performed without mortality. In September 1939 these cases were presented in greater detail.⁷ This series has now been extended to ten surgically treated children and adults,⁸ observations from which form the basis of the present communication.

Fig. 1.—Appearance of 11½ year old girl (patient 5) showing the slender, underweight habitus which is common in children with a large patent ductus arteriosus. Patient's weight 57 pounds (26 Kg.); expected average normal, about 75 pounds (34 Kg.).

SYMPTOMS AND SIGNS

There has been a widespread tendency to classify individuals with a patent ductus arteriosus merely as having "congenital heart disease," but now that surgical therapeutic procedures are available for alleviation or

cure of this lesion it is important to find the ways in which the abnormality can be recognized. Considerable study of the problem has convinced me and my medical confrères that the correct diagnosis can be made with a high degree of accuracy. The basis for this statement lies in the fact that a patent ductus was found in each of the cases in which exploration was done and in only one child was there an additional cardiovascular abnormality. It is therefore worth while listing the symptoms and signs which are now believed to be characteristic of the patent ductus.

The physical manifestations of this lesion may be entirely lacking in infancy and are apt to be confusing in the first two or three years of life but are almost always typical after the fourth year. Auscultation of the heart at birth or shortly thereafter may give negative results. This is exemplified by patient 6, who, though several competent observers heard no murmurs during the first year of life, was found to have a very loud murmur at 4 years of age. More commonly the patient has a murmur during the neonatal period which is difficult to place and time accurately because of the rapid heart rate, the fast respirations and the small size of the chest. As a child reaches the third or fourth year of life, a murmur develops which has several rather distinct features. It is continuous but is accentuated during systole. In whole or in part it is widely transmitted over the precordium, to the axillae and to the back, but it has a maximum loudness in the second or third interspace to the left of the sternum. In contrast to the "blowing" or "harsh" murmur of pulmonic stenosis or coarctation of the aorta, it has an unmistakable rumbling quality which is well described by the term "machinery murmur." The second pulmonic sound is almost always increased in intensity (if it is not overshadowed by the intense murmur), in contrast to the diminished or absent second sound in stenosis of the pulmonic valve. Cases are described in the literature as presenting only a systolic murmur (the ductus presumably being small) but in all of our cases the murmur was a continuous one.

A very coarse, precordial thrill, systolic in time or continuous with systolic accentuation, and most prominent over the pulmonic region, was a routine observation. Some did not develop this until the third or fourth year of life, and indeed cases have been observed in which the ductus is small and a thrill absent. The thrill may be quite intense and the patient or another member of the family is often conscious of a "buzz" within the chest.

The heart is usually slightly enlarged. It has a beat of accentuated vigor and a rate which is possibly somewhat increased. Following exercise the heart rate and the intensity of beat are above the expected normal response.

The blood pressure shows no significant change in its systolic level, but there is a low diastolic figure if the ductus is large. Thus the leak from the aorta may be sufficient to produce a significant fall of peripheral pressure when the aortic valve is closed (during diastole). If this loss is great enough, a water hammer pulse or a visible capillary pulsation can be detected on examination of the peripheral vascular system.

The physical development of the individual may be retarded, but this is not universally true. About half of our patients were underweight and quite slender, as depicted in figure 1. When patency of the ductus is the sole lesion, cyanosis is never observed unless the heart is failing and death is impending.

8. These cases were extensively studied and referred for treatment by Dr. J. P. Hubbard, cases 1 and 3; Dr. J. P. Hubbard and Dr. L. K. Diamond, case 6; Dr. W. R. P. Emerson and Dr. Hyman Green, cases 2 and 5; Dr. C. S. Burwell and Dr. E. C. Eppinger, case 4; Dr. S. A. Levine and Dr. Fresenius Van Nuyse, case 7; Dr. J. E. Carroll of Hartford, Conn., case 8; Dr. P. D. White and Dr. H. B. Sprague, case 9, and Dr. K. D. Blackfan, case 10.

The history may reveal varying degrees of cardiac embarrassment. If the ductus is small, no impairment of physical activity will be found; if the fistula is large, a moderate but definite limitation in exercise is the rule; if the ductus is widely patent, frank failure may supervene. In one of our patients (17 years old) there had been recurring bouts of palpitation, dyspnea and

Fig. 2.—Seven foot roentgenogram (patient 8) showing three appearances usually associated with patent ductus arteriosus: (1) increased cross diameter of heart (transverse diameter of heart 10 cm., internal diameter of chest 17.6 cm.); (2) increased prominence of pulmonary artery (indicated by arrows) (3) vascular congestion in lung fields. The heart was unusually active, as shown by fluoroscopic and kymographic studies.

peripheral edema for many years, while a woman of 26 had marked orthopnea for three years. In rare cases there may be sudden collapse or death, much the same as that encountered with aortic valve insufficiency.

larger volume of blood per minute and the right ventricle must pump against a raised pressure in the pulmonary arteries. An additional load therefore falls on both sides of the heart, and it is not surprising to find that the electrocardiogram usually shows no axis deviation. In only one of our ten cases was there any axis-deviation, a slight left preponderance being present in case 8; the other nine gave normal tracings. Well authenticated cases have been described in which there was a definite left axis or right axis deviation, but the finding of an abnormal electrocardiogram should at once arouse suspicions of some other cardiac lesion. This is particularly true of right axis deviation, which is suggestive of pulmonary valve stenosis.

ROENTGENOLOGIC OBSERVATIONS

Because the roentgenologic changes in the heart, great vessels, and lungs are being presented by Dr. Eppinger⁹ I will not describe them here. Suffice it to say that the finding (fig. 2) of cardiac enlargement, prominence of the pulmonary artery, increased pulsation of the heart and great vessels and pulmonary congestion is not enough in itself to warrant making a diagnosis of a patent ductus arteriosus. However, it is valuable confirmatory evidence in establishing this diagnosis when evaluated with the clinical history, physical observations and electrocardiographic studies.

INDICATIONS FOR OPERATION

When it is reasonably certain that a given person has an uncomplicated patent ductus arteriosus, the question arises whether or not surgical obliteration of this vessel should be performed. The dangers of the untreated abnormality must be balanced against the possible hazards of operation. If the patient's chances for developing important complications appear to be relatively high, the risks of surgery can be taken with impunity. Hubbard, Emerson and Green¹⁰ have

pointed out that each case should be evaluated, for by no means should all these individuals be subjected to operative treatment. The fact that some people live a relatively long and active life (particularly if the ductus is small) should make the clinician cautious in advising surgical treatment. It is possible that views may change as experience is broadened, but the following points sum up our present attitude with regard to criteria for selection of cases for surgery:

Shortcircuiting of blood through the fistula can so diminish the peripheral flow that the physical development is significantly retarded. When this occurs there is clearly a justification for closure of the ductus. This indication for operation is largely concerned with children from 5 or 6 years up to adolescent ages.

The deviation of blood by way of the shunt may be counter-balanced (in some cases) by an appreciable increase in the left ventricular output per minute. In this way the peripheral flow of blood can be maintained at or near normal and the individual will develop properly; but in attaining these ends the heart is so overworked that it eventually fails. Physiologic studies on some of our older patients⁴ clearly show that the left ventricular output was two or three times the expected normal, and hence it is easy to understand why cardiac failure should occur. While decompensation appeared in case 4 at the age of 6 years, it is rarely seen before puberty. If it is ever to be a serious menace, it almost invariably manifests itself before the age of 30. In other words, if a man or woman has arrived at the age of 30 or 35 without history or evidence of decompensation, the chances are good that it will not be found at

ELECTROCARDIOGRAPHIC OBSERVATIONS

When the ductus arteriosus remains open the left ventricle must pump a

The chest is entered through the second interspace and the second and third costal cartilages have been cut. The pleural covering of the mediastinum will be opened along the dotted line.

a subsequent period. The presence of (or history of) cardiac failure in any form is a definite indication for operation. This should be extended to include any cardiac embarrassment, even though frank failure does not exist. Under this broad category would be appreciable enlargement of the heart, undue increase in its

rate and beat after mild exercise and overactive cardiac impulse by physical or fluoroscopic examination.

In the presence of a patent ductus arteriosus, the lungs receive blood from the venous circulation by way of the right ventricle, and in addition blood pours

formed is only a ligation of the ductus, and while complete obliteration of the vessel can be accomplished in some cases, there are others in which a tiny pinhole opening persists no matter how tightly the ligatures are applied. These facts are evident by the complete absence of postoperative murmurs in some cases and persistence of minimal ones in others. It is therefore evident that ligation of a ductus can greatly diminish the mechanical burdens of a heart and can improve the peripheral circulation of the patient, but at the same time a small opening can maintain some swirling of pulmonary artery blood and still keep alive the danger of subacute bacterial endocarditis. I therefore believe that—with the operation which is now practiced—there is little justification for submitting individuals to surgery solely for the theoretical prevention of future endocardial or pulmonary artery infection. If, however, a method can be devised whereby the ductus is completely divided and the operative mortality can be kept at a low figure, then it would be worth while operating on practically all these patients in the hope of diminishing subsequent endocarditis or endarteritis. Toward the goal of developing a method for safely dividing the ductus I have spent considerable time in the laboratory and have found a way which promises to furnish this additional step without undue risk. The opportunity has not yet presented itself to attempt this in a human case.

A final discussion of indications for operation is concerned with the individual who already has a superimposed *Streptococcus viridans* infection which will presumably terminate fatally. Theoretically, closure of the ductus may diminish eddying of blood in the pulmonary artery, limit the formation of bacterial vegeta-

Fig. 4.—Details of operative exposure of the ductus: 1. Base of heart and great vessels; parietal pleura being opened along the dotted line. 2. Presenting fat and areolar tissue dissected to isolate the recurrent laryngeal nerve. 3. Ductus completely freed of overlying fat. 4. Posterior wall of ductus freed by blunt dissection. 5. in at high pressure from the aorta. It is therefore evident that the amount of blood in the pulmonary vascular bed is greater than normal, the increment depending directly on the size of the ductus and the pressure within the aortic arch. Because of this increased volume of pulmonary blood, the vital capacity is reduced and orthopnea may appear. Thus, orthopnea per se is not necessarily evidence of a failing heart, but indeed it might be brought about by an overcompensated left ventricle which is forcing increased amounts of blood into the aorta and thereby into the lungs. The striking symptomatic improvement in a woman of 26 (case 9) who had had orthopnea for three years has certainly made this symptom an indication for operation.

Regarding the dangers of a future *Streptococcus viridans* infection as a justification for operation, I believe there is considerable room for debate. Theoretically, if the fistula could be closed off and the swirling of blood in the pulmonary artery be thereby abolished, the subsequent incidence of fatal bacterial infection would probably be reduced. However, the operation which I, and subsequently others, have per-

Fig. 5.—Patient 2 on first postoperative day. These patients have little discomfort if the operative procedure is carefully done.

tions and permit existing ones to be better treated by chemotherapy. This optimistic view must be discounted by the fact that a ductus or pulmonary artery which is the seat of bacterial vegetations is apt to be eroded and friable and hence may rupture if disturbed by the surgeon's manipulations. Tourouff¹¹ has recently oper-

11. Tourouff, A. S. W.: Personal communication to the author.

ated on four such patients. Two died on the table from fatal hemorrhage, one still has positive blood cultures fourteen weeks after operation and a fourth has been apparently cured of her bacteremia sixteen weeks after operation. It can be argued that any risk is defensible

which offers the least hope of curing these desperate cases. I have not yet subscribed to this rationale, because some individuals with subacute bacterial endocarditis live many months in fairly good general health while a surgical patient with a ruptured ductus will probably be dead in a few minutes. Hence I have not chosen to treat such persons surgically; but further experience may show that the operation has merit if used when the infection is of short standing and the vessel walls are not yet ulcerated and thinned out.

OPERATIVE TECHNIC

It is not within the scope of this presentation to describe extensively the operative technic, which has been given in detail in previous communications.¹² Briefly, the ductus can be adequately and safely brought into view by an approach through the left anterolateral chest wall (fig. 3), traversing the left pleural cavity, temporarily collapsing the left lung, opening the parietal

pleura of the mediastinum (fig. 4) and then dissecting down between the great vessels. The cutaneous incision can be made above or below the nipple, and in the adult woman it could be made below the entire breast. Entry through the second space gives a good exposure, provided the intercostal muscles are divided well around into the axilla. Great care and patience must be exer-

cised in freeing up and isolating the ductus for fear of injuring it or the regional structures. The ductus has always been so short that I have not dared to divide it in any instance. Heavy braided waxed silk ligatures were used in all of these cases and this was supplemented in the more recent ones by injecting a sclerosing fluid between double ligatures. It is difficult to describe just how tightly the ligatures must be applied, for this can be determined only by experience with some of these operations. If the ties are too loose, a small fistula may persist; if they are too tight there is danger of their cutting through the vessel. Following ligation of the ductus, the left lung is reexpanded with positive pressure by the anesthetist, and the chest is closed.

The anesthetic in eight cases was cyclopropane, but in the other two ether in a closed system served quite well. In no case has an intratracheal tube been used, since a tightly fitting face mask adequately permitted positive pressure expansion of the lung whenever this was necessary.

If the operation is carefully done, it is tolerated very well and there is little postoperative reaction (fig. 5). Some of these patients have been out of bed on the first or second day, and hospitalization of more than seven to ten days after operation is seldom necessary.

RESULTS OF OPERATION

In the present series of ten¹³ surgically treated patients (table 1) one died two weeks after operation from a Staphylococcus aureus infection and one proved to have a complicated cardiac abnormality and has derived only slight benefit from operation. The other eight individuals have all shown a progressive and gratifying improvement. The ways in which they have been altered may be analyzed as follows:

Patients 1, 2, 3, 5 and 7 each had important retardation in physical growth prior to operation. The first four of these have now been followed long enough to gain a clear idea of the results of the surgical undertaking. It has been surprising to observe the physical alterations which are typified by the weight gains shown in table 2. This postoperative change was most marked in case 2, in which there was a gain of 22 pounds (10 Kg.) in eighteen months after ligation of the ductus. These augmentations in weight have been particularly significant since they occurred in children who previously were thin and poorly nourished, in spite of medical efforts to combat this condition. In short, closure of the fistula allows more blood to flow to the periphery, so that the physical development is improved.

Fig. 6.—Typical blood pressure before and after ligation of a patent ductus arteriosus (case 5). If the ductus is large, the diastolic pressure is low. On ligation of the ductus, the diastolic pressure immediately rises to normal.

13. Since completion of this manuscript two more patients, aged 22 months and 7 years, have been successfully operated on. There has been complete disappearance of the murmurs in both of them.

12. Gross (footnotes 6 and 7).

A rise in diastolic blood pressure was found after operation in each case. In case 6 the ductus was relatively small and after its ligation the diastolic pressure rose only from 10 to 15 mm. of mercury. In all other cases (including case 7) there was an immediate rise of the diastolic level from its low preoperative level of 30 to 50 mm. of mercury to a normal value of 70 to 75 (fig. 6). In some cases there was a tendency for the diastolic pressure to be slightly higher than normal for from five to seven days after operation, following which it assumed a normal value.

The physical activity of patient 6 has been improved to only a slight degree, but in the other eight surviving individuals there has been a definite improvement in capacity for exercise. This has not been quantitatively tested on a treadmill or other mechanical device, but patients have volunteered the information that they "could run farther," that the "heart did not speed up the way it used to," that there was "no more palpitation" after moderate exercise, that "the heart does not pound the way it did formerly," and so on. An improved peripheral circulation was spontaneously noticed by several patients, who found that their feet and hands were warmer than they had been previously during cold weather, and this observation was further substantiated by physical examination of the extremities.

One individual (patient 4) who had had attacks of frank cardiac decompensation as often as two or three times a year before operation has now gone eighteen months since operation without evidence of failure at any time, in spite of the fact that she has been indulging much more in outdoor sports.

Finally, there was a 26 year old woman (patient 9) who would become dyspneic from light housekeeping duties and who had been primarily bothered by orthopnea, which necessitated sleeping in a semisitting position for the last three years. Under observation in the hospital she could not be encouraged to lie down flatly on a table or bed for more than from ten to fifteen minutes because she would become choked up, uncomfortable and short of breath. Since operative ligation of her patent ductus, she carries on normal household work and has been able to sleep all night in a flat position without any difficulty.

SUMMARY AND CONCLUSION

The accuracy with which it is possible to make the diagnosis may be judged by the fact that exploration was done in ten cases and a patent ductus found in each. In only one case was there another cardiovascular abnormality. Operation should be advised only for carefully selected cases. With the procedure which is now employed (ligation), it is not felt that complete obliteration of the vessel can be accomplished in all cases; hence it is not believed that all individuals with a patent ductus arteriosus should be operated on in the hope of preventing subacute bacterial endocarditis. If, however, a procedure can be developed by which the ductus can be completely but safely severed, it will be justifiable to employ the operation more extensively to diminish the incidence of *Streptococcus viridans* infection. A review of our material shows that ligation of the patent ductus arteriosus is productive of excellent postoperative results when used for patients who have retarded physical development or evidence of cardiac embarrassment.

THE MECHANICAL EFFECTS OF PATENT DUCTUS ARTERIOSUS ON THE HEART

AND THEIR RELATION TO THE X-RAY SIGNS

EUGENE C. EPPINGER, M.D.

AND

C. SIDNEY BURWELL, M.D.

BOSTON

The appearance of the heart shadow on the x-ray film or screen is determined partly by the structure of the heart and partly by what William Harvey called "the movements of the heart and blood." The dynamic events which accompany the pumping of blood influence the size and shape of the shadow, the excursion of its borders, the pulsation of the great vessels and even the volume of blood in the adjacent lungs. Much has been learned about the dynamics of the heart through the medium of the x-rays; it is possible that something may be learned about x-ray signs by a study of circulatory dynamics.

The brilliant operation described by Gross¹ provided the opportunity for making measurements of the circulation of patients with patent ductus arteriosus.

Fig. 1.—The flow of blood in a normal person.

Figure 1 illustrates the flow of blood in a normal heart. In a resting individual about 4 liters of blood per minute returns from the periphery and the same amount is pumped out by the right ventricle, passes through the lungs, enters the left side of the heart and is pumped out by the left ventricle. It is thus clear that the outputs of the right and left ventricles are essentially identical in the normal individual. However, a different situation is created by a patent ductus arteriosus, since the ductus arteriosus connects the aorta with the adjacent pulmonary artery (fig. 2).

Studies made on Gross's patients have led to the acquisition of important information with regard to the circulation in these patients, which may be summarized as follows:

1. A stream of blood flows from the aorta to the pulmonary artery through the ductus; this flow is going on during both systole and diastole. This blood, shunted from the aorta without having gone to irrigate the periphery, returns through the lungs to the left side of the heart which it just left. Thus, the shunted stream serves no useful purpose. It should be emphasized that this is not a situation in which venous blood enters the

arterial system but one in which arterial blood is entering the pulmonary system. Since blood in the arterial system is not diluted by venous blood, these patients are not cyanotic. Under the conditions of operation from 45 to 75 per cent of the blood pumped out by the left ventricle into the aorta passes back through this short circuit into the pulmonary artery (Eppinger, Burwell and Gross²).

Fig. 2.—The flow of blood in a patient with patency of the ductus arteriosus.

2. That portion of the blood in the aorta which is not shunted goes to the periphery and returns to the right ventricle. Therefore, a situation is created in which the right ventricle has only one source of blood (i. e. the peripheral circulation) while the left ventricle has two sources of blood (i. e. the blood from the right ventricle and the blood returning through the short circuit). In the cases studied the left ventricle had to pump from two to four times the amount of blood put out during the same time by the right.
3. The leakage of blood from the high pressure aorta to the lower pressure pulmonary artery is accompanied by a fall in the peripheral diastolic pressure and a slight rise in the pulmonary artery pressure. To emphasize the magnitude of these changes we present in table 1 the actual measurements of the blood flow before and after operation.

Fig. 3.—Anteroposterior appearance before and after ligation of the ductus.

These deviations from normal in the movement and distribution of blood suggest certain signs which should be sought in the x-ray examination by film, fluoroscopy and kymogram.

- These include the following:
1. The greatly increased output of the left ventricle indicates the possibility of the enlargement of this chamber.
 2. Eppinger, E. C.; Burwell, C. S., and Gross, R. E.: The Effects of Patency of the Ductus Arteriosus on the Circulation, to be published.

2. Since both the left ventricle and the pulmonary artery are transmitting with each beat an increased volume of blood, they may be expected to show an increased pulsation.
3. Since the pulmonary artery receives blood from two sources, and since it has been seen at operation to have overflowed, the silhouette of this artery may exhibit unusual prominence.
4. Because of the increased flow of blood into them, the pulmonary vessels may show the signs of engorgement.
5. The combination of increased inflow and engorgement may lead to increased pulsation of the pulmonary artery branches.
6. If a normal mitral valve is not wide enough to transmit this large amount of blood without an elevated left auricular pressure, there may be a visible dilatation of the left auricle. (It may be mentioned that one of our patients before operation showed a mid-diastolic apical murmur characteristic of mitral stenosis. Since ligation of the ductus this murmur has never been heard.)

These six signs were then sought in the films and in the recorded fluoroscopic examinations of the nine patients operated on by Gross. In this search we had

TABLE 1.—Actual Measurements of Blood Flow Before and After Ligation of the Ductus

Patient Number	Blood Flow Before Operation		Volume of Shunt, Liters	Percentage of Shunt	Blood Flow After Operation, After Peripheral and Pulmonary, Liters	
	Peripheral, Liters	Pulmonary, Liters			Peripheral, Liters	Pulmonary, Liters

TABLE 2.—Occurrence of the Predicted X-Ray Signs in Patency of Ductus Arteriosus

	Patient								
	1	2	3	4	5	6	7	8	9
Left ventricle enlargement.....	++	++	++	++	++	0	++	++	++
Increased pulsation of left ventricle and pulmonary artery.....	++	0	+++	+++	++	+	++	×	+
Prominent pulmonary artery.....	++	++	++	+	+	+	?	+	++
Pulmonary congestion.....	+++	++	++	++	++	+	+++	++	++
Dilated left auricle.....	++	+	+	+++	+	×	+	+	+
"Hilar dance".....	++	0	0	0	+	0	0	0	+

the indispensable aid of Dr. M. C. Sosman and Dr. G. M. Wyatt.

The frequency with which these signs were found is shown in table 2. An attempt was made to estimate the degree of deviation from the normal, which is expressed as 1 +, 2 + or 3 +.

Left ventricle enlargement of a moderate degree was present in eight of the nine cases. Increased pulsation of the left ventricle and pulmonary artery was present in seven of eight and not recorded in one case. A prominent pulmonary artery was observed in eight out of nine and was questionable in one. Perhaps the absence of visible prominence in this one case was due to the great enlargement of the left auricle, which may have obscured the shadow of the pulmonary artery. An increased volume of blood in the pulmonary vessels (pulmonary congestion) was demonstrable in all cases. A dilatation of the left auricle, usually of mild degree and best seen in the right anterior oblique view, was observed in the eight cases in which appropriate plates were made. The so-called hilar dance of traditional value was present in only three of the nine cases.

Examples of some of these observations are shown in figures 3, 4 and 5, in which the x-ray phenomena before and after ligation of the ductus are demonstrated. Figure 3 is a reproduction of seven-foot plates of the heart before and after operation. They illustrate the enlargement of the left ventricle, the prominence of the

Fig. 4.—Right oblique appearance before and after ligation of the ductus.

pulmonary artery and pulmonary congestion, all of which are less marked after the operation. Figure 4 is a reproduction of films taken obliquely and illustrates particularly the change in the size of the left auricle which followed ligation of the ductus. The x-ray kymograms (fig. 5) illustrate in some degree the increased pulsation of the left ventricle, the pulmonary artery and the pulmonary artery branches, although these pulsations were more clearly observed on the fluoroscopic screen. There is an impressive contrast between the violently overactive left ventricle with the ductus open and the relatively calm left ventricle after ligation.

CONCLUSIONS

The analyses of these cases leads to the conclusion that the x-ray signs suggested by the observed changes in the circulation are usually present in patients with patent ductus arteriosus.

Fig. 5.—Kymogram before and after ligation of the ductus.

On the whole the signs are not sufficiently specific to supply final testimony concerning the diagnosis of patent ductus arteriosus. However, if the relation of these x-ray signs to the dynamics of the circulation is understood, appropriate x-ray studies may (1) suggest the diagnosis, (2) contribute important confirmatory evidence and (3) bear important witness as to the effectiveness of therapy.

721 Huntington Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. GROSS AND DRS.
EPPINGER AND BURWELL

DR. CLAUDE S. BECK, Cleveland: Rarely in this day does a surgeon perform an operation that will be recorded in the pages of medical history. Nevertheless, this was accomplished by Dr. Gross when he successfully placed a ligature around a patent ductus arteriosus. This operation, done in August 1938, ended a forty year period of sporadic and casual interest and began an era which in two years has produced many successful cases. As far as can be determined from the literature, the original idea came from John Monro of Boston, who carried out dissections on infants and proposed the operation to the Philadelphia Academy of Surgery in 1907. There is no record of the operation having been attempted by Monro. In 1924 Holman and I carried out experiments in which we attempted with some measure of success to prevent the patent ductus from closing in newly born dogs. This was done by producing a stenosis of the pulmonary artery. We, as well as a number of other surgeons, were interested in applying the idea to patients, but there were no patients for operation. The operation had never been performed and the medical men who saw these patients did not have them operated on. For this reason I believe I should mention the name of John Hubbard, who referred the patient on whom the first successful operation was done. The first attempt to carry out the operation was by Strieder in 1937. Strieder's patient had bacterial endarteritis before operation, and at operation an anatomic condition was found which made the passage of a ligature impossible. Plication sutures were used and the communication was not completely closed. The bacterial infection persisted and the patient died several days after operation. These ten operations by Gross are a most amazing record of success. To these can be added other records of achievement—thirteen patients by Bullock, Jones and Dolley of Los Angeles, one by Bigger of Richmond, one by Gurd of Montreal and one or more by Holman of San Francisco. Last week at the meeting of the Thoracic Surgical Association in Cleveland, Touroff and Vesell reported operations on four patients with bacterial endarteritis and septicemia. These heroic operations in cases of infection deserve special comment, because one patient has been free from infection for nineteen weeks since operation, one has had improvement in the circulation but infection persists seventeen weeks after operation, and two died of hemorrhage at operation. It would appear, therefore, that the presence of infection in the blood stream is not always a contraindication to operation. Touroff believes that active vegetations in the left side of the heart or in the aorta preclude operative intervention. If the infection is recent in terms of days or weeks so that significant vegetations have not formed, it would appear that success is still possible. Perhaps one can look forward to the day when the defect in the aorta and the pulmonary artery can be closed by direct arterial suture.

DR. WILLIAM D. STROUD, Philadelphia: Ever since hearing the discussion of this operation at the St. Louis session last year, I have been skeptical concerning it. Congenital heart cases fall into three classes: The first includes those in which the maldevelopment was so great that a few days, a few weeks or a few months was all the patient could expect. The second group includes cases showing clubbing of the fingers and toes, marked cyanosis and breathlessness with poor physical development. Here all the physician can do is to encourage the family and attempt to arrange proper educational facilities, occupational therapy and vocational training until tuberculosis, pneumonia, subacute infective endocarditis or heart failure causes the end. The third group, and the one in which I had always considered patent ductus arteriosus, includes patients with signs of congenital maldevelopment of the heart but in whom it apparently has very little effect from the standpoint of development, length of life and circulatory efficiency. The cardiologist's job in these cases was to persuade the family and the patient he was not a hopeless cripple, which other physicians had persuaded him he was. Last Friday Dr. Shapiro read an interesting paper on this subject before the American Heart Association. He feels, as I

had felt until this morning, that bacterial endocarditis is relatively rare in these cases. I was much surprised to hear from Dr. Gross that it occurred in 40 per cent, and he may be right. I looked up ten patients whom I had seen in the past twenty years. So far none of them had died or shown evidence of congestive heart failure and none have developed bacterial endocarditis. I therefore feel we must be careful in considering this operation merely because of the possibility of bacterial endocarditis. A discussion as to whether or not an operation is indicated after bacterial endocarditis has developed is interesting because of recent reports of successful removal of arteriovenous aneurysm in which bacterial endocarditis has developed. I should like to ask whether there is any truth in the suggestion that this operation might be contraindicated as other congenital defects are so common with a patent ductus arteriosus and that the latter might be a compensatory mechanism, especially in the presence of congenital pulmonary stenosis with or without a patent interventricular septum. From what the authors said, the blood is just shunted back and forth through the patent ductus arteriosus and therefore is of no value. If this is true I cannot see how a patent ductus arteriosus could be a compensatory mechanism. The improvement in bodily development following this operation is most interesting. Some of my patients are definitely underdeveloped in spite of the fact that they have no breathlessness or apparent circulatory insufficiency. Perhaps such maldevelopment is a worthy factor in considering this operation.

DR. HARRY VESELL, New York: Praise is due Dr. Gross for showing that this operation can be done with reasonable risk and success in uninfected cases. I want to confine my remarks to cases of patent ductus arteriosus in which bacterial infection is superimposed. Dr. Touroff and I had the good fortune of observing a woman aged 29 who had patent ductus arteriosus with a superimposed infection which we considered rather severe because of the presence of a large number of colonies in the blood cultures. Two were taken before operation; one in the flask showed a great number, and one that was plated out showed 400 colonies per cubic centimeter. The patient had a very septic temperature. After a week she was operated on. Several days after operation, two successive blood cultures were negative. Six or seven further blood cultures were taken and they were negative. She had a more or less uneventful course thereafter and is now, nineteen weeks after operation, back at work and feeling perfectly well. One point that I wish to emphasize is the question of valve infection in these cases when subacute infection is superimposed. Cases collected particularly by Dr. Blumer indicate that infection of the valves does occur, and as indicated by Dr. Blumer and also Dr. Abbott this valve infection is a more or less late phenomenon. In spite of the fact that many cases have been observed to go along for a period up to two years and then come to autopsy, a considerable percentage of them, even after that period of time of infection, up to two years, failed to show infection of the valve. Certainly infection of the aortic and mitral valve would be a great handicap to any expectation of success from the operation. In view of the fact that these valve infections occur late, I think it is incumbent on us, if we consider the operation at all, to have it done very early, just so soon as the diagnosis of infection on the patent ductus can be made.

DR. MAUDE E. S. ABBOTT, Montreal: I am very happy to have the opportunity of hearing Dr. Gross. He has revolutionized the outlook on the therapeutic aspects of congenital heart disease. Of course, the patent ductus does seem the most gettable anomaly for surgical intervention, but we have not ended there and it is a great event in this field. The fact that he has done nine cases successfully and in such a simple way, with recovery so quickly as in the first several of these cases, is really miraculous. I believe the most favorable time, as said by Dr. Gross and the others who have operated, to be in early childhood; that is, 7 or 8 to 10 or 12, because, as the last speaker pointed out, of the likelihood of the later development of infective valvular disease. We all know that the first onset one sees of bacterial endocarditis is around the pulmonary end of the ductus and these later valvular lesions come on after some little time, so the favorable time is before the onset of widespread subacute bacterial endocarditis. I had the oppor-

tunity in March of seeing one of Dr. Touroff's patients, a girl of 18 who had been successfully operated on, January 27. She had a large number of colonies in the blood stream and is now apparently quite free from infection with no fever, the blood culture is sterile and she is back at her office work apparently in perfect health. This is a great record of achievement. If the operation extends to cases of bacterial infection, a much more difficult and hazardous field, of course, it is a big thing, because this is the most serious complication that awaits these individuals.

DR. M. J. SHAPIRO, Minneapolis: I have been greatly stimulated by the work of Drs. Gross, Eppinger and Burwell. I have had nineteen patients with patent ductus arteriosus since 1922. The main reasons for doing this operation are, first, to hope to prevent subacute bacterial endarteritis and, second, to prevent congestive heart failure. I did not say in my paper that subacute bacterial endo-arteritis and congestive failure are rare, but I said that the statistical evidence in the literature is not clear as to how often these complications occur. The figure of 25 per cent or 40 per cent of subacute bacterial endocarditis in patent ductus arteriosus is based almost entirely on pathologic studies. I believe that most of these cases that were studied pathologically were unusual. I know from postmortem examinations that, when the ordinary postmortem examination is done, the ductus arteriosus is missed. I believe that patency of the ductus must be more common than is appreciated. There have been some very unsatisfactory results with this operation. Dr. Gross deserves the utmost praise for his achievement, yet there have been other excellent surgeons who have attempted this operation and have failed. Of my nineteen patients only one or two were maldeveloped. I have been impressed with the unusually good physical condition in this group. In regard to the question of subacute bacterial endarteritis, we know that one of Dr. Jones's patients died about forty-five days after the operation of subacute bacterial endarteritis which developed at the point of ligation. Interestingly enough there was recanalization of the duct. I believe some of the patients who have been operated on are not any different from the group of patients I have followed, some of them as long as seventeen years, and who showed no evidence of cardiac failure. Not one of my nineteen patients has developed subacute bacterial endarteritis, and only one patient died after surgery. I believe that surgical operation should remain for those patients who give evidence of enlargement of the heart. These patients should not be operated on when they are young unless one can prove by observation that the vessels in the lungs are getting larger, the heart is increasing in size and there is some evidence of congestive failure. In regard to operating on patients with subacute bacterial endarteritis, I should be in favor of operating on every one of them because at the present time we have nothing to lose.

DR. HAROLD E. B. PARDEE, New York: I have not had great personal experience with cases of congenital heart disease. I have felt as Dr. Stroud does that it has been a comparatively uninteresting subject from the point of view of treatment. I feel, however, that this surgical procedure marks a tremendous advance and warrants considerable discussion. It has great promise and with further development the present operative mortality will be greatly reduced. I do not believe that we know what the operative mortality is at present. I do know that of two reported series totaling thirty cases there have been two deaths, which is a mortality of about 7 per cent. We have heard at this meeting of a couple of other cases in which death occurred and which have not been reported, so that I believe that in the hands of the general surgeon not yet familiar with the operation the mortality is much higher than 7 per cent. Situations must arise during the operation which I am sure Dr. Gross will be able to tell us about, which make it extremely difficult in certain cases to perform the operation successfully. I am convinced that Dr. Stroud and the last discussor are correct that the importance of bacterial endocarditis as a complication has been overemphasized. This is almost of necessity so, because the most statistics are collected from the literature of reported cases. There is a glamor connected with bacterial endocarditis which would lead a physician having such a case to report it. The same patient dying of heart failure would not attract the same attention. We do not even know that this operation will

prevent the subsequent development of bacterial endarteritis on the site of the orifice of the patent ductus which has been obliterated, because the surface of the aorta at this point may be congenitally structurally defective and so still may acquire the infection later in life. I am not sure that nineteen years is long enough to follow these cases. I think it ought to be thirty-nine. I feel that at present the operative indication should include only cases which show evidence of cardiac insufficiency—that is, limitation of ability to exercise—cases that show considerable cardiac enlargement, especially those with progressive enlargement under observation and cases that show nutritional deficiency. If we operate for one of these three reasons, we have a sound reason for the operation because without it the patients will progressively grow worse. I should not operate on a patient who is apparently doing well, who is well nourished, who does not show signs of cardiac insufficiency and who does not have much cardiac enlargement.

DR. WILLIAM J. KERR, San Francisco: This operative procedure has opened up a new era in the study and treatment of heart disease. I wish to record an experience which I have had in two cases with operative procedures and to suggest that perhaps others will be found in the same category. The first patient was a woman in her twenties who was beginning to show signs of congestive failure with irregularities in rhythm. She had all the symptoms and signs of patent ductus arteriosus and probably had no other complications in the heart. At the time of operation, performed by Dr. Harold Brunn of San Francisco, it was rather difficult to find the patent ductus. Something was found which on having a ligature placed about it seemed to shut off the murmur and cause a change in the peripheral blood pressure readings at the time. The patient during the next several hours developed symptoms of severe infection, and *Staphylococcus aureus haemolyticus* was present in the fluid removed from the wound. The patient lived for two days. At autopsy it was found that there was no patent ductus arteriosus, but a fistulous opening connected the lumen of the arch of the aorta and the left branch of the pulmonary artery, the opening being 7 mm. in diameter, and it would not have been possible, excepting under procedures mentioned by Dr. Beck, I believe, to have separated the vessels and suture them. In connection with this case, which may be similar to one reported by Dr. Gross in which *Staphylococcus aureus* also was found, the question came up in my mind whether the staphylococcus came from the patient or from the audience; those who were inlookers at the time of this procedure may have brought the organisms to the patient. The other patient was a child who, following the operation, which was not difficult, continued to have a murmur although the peripheral signs and symptoms cleared up and apparently the child is in good condition. It brings up a problem which has been repeatedly raised and thought of by most of us. There may be multiple lesions. There may be some narrowing of the pulmonary artery or the pulmonary valve or an opening in the septum in these patients; but if it is adequate to carry on circulation, the patient certainly would be much improved.

DR. ARTHUR E. STRAUSS, St. Louis: There are two factors worthy of more emphasis. First, the factor of the type of bacterial endocarditis which we usually see in patent ductus arteriosus. We know from autopsy material—and it is confirmed by the experimental work on infectious endocarditis—that the site of the bacterial infection is usually the site of trauma, and the bacterial endocarditis in patent ductus arteriosus is usually originally located in the pulmonary artery opposite the inlet of the ductus. If that is the case and if these other infections of the valve are secondary, it seems at least reasonably possible that such bacterial endocarditis may be avoided if the constant trauma of this forcible aortic stream can be stopped by ligation. The other point has already been referred to twice, but from the clinical point of view it cannot be emphasized too strongly; that is, that the diagnosis of patent ductus arteriosus, while from the discussion seemingly simple, is not always so, and we cannot be sure in a great proportion of the cases that there are not other accompanying congenital anomalies.

DR. ROBERT E. GROSS, Boston: It is timely and valuable to have the study which Dr. Shapiro has presented. When com-

bined with the recently published data summarized by Dr. Bullock of Los Angeles, we are now beginning to have a better idea of the prognosis in cases of patent ductus arteriosus. Dr. Shapiro has probably painted a too optimistic picture for the individuals who are left untreated. I know of a family with three children, each of whom has a patent ductus arteriosus. One died in early life, one now has subacute bacterial endocarditis and the oldest has ventricular fibrillation—making this a decidedly important lesion as far as this family is concerned. Many other cases could be cited to emphasize that the patent ductus is not always a harmless lesion. The World War veteran mentioned by Dr. Stroud raises a point regarding criteria for operation. I have an impression that an individual who reaches the age of 35 or 40 years without history or evidence of cardiac embarrassment or endocarditis is not likely to develop these at a later date. Hence operation should not be done after the third decade to prevent some theoretical future disability and should be done only if there are some very definite indications. Regarding the possibility of other cardiovascular abnormalities being associated with a patent ductus arteriosus, it is true that the loud murmur may overshadow the signs of other defects. However, in only one of our cases was there an associated abnormality, and in this instance the ductus was not acting as a compensatory mechanism. A word of caution is in order. The discussers have mentioned some of the pitfalls which may be encountered during or after these surgical procedures and it is obvious that this operation should not be performed without considerable deliberation. Furthermore, a surgeon who is not willing to study various forms of congenital heart disease, who does not familiarize himself with abnormalities which he may encounter in the operative field, who does not thoroughly learn the local anatomy and who does not practice the procedure on cadavers and animals should not risk the life of a patient by embarking on this undertaking, which may lead either to beneficial results or to a disastrous ending.

DR. C. SIDNEY BURWELL, Boston: You may think that this discussion has gotten away from the field of radiology, but I assure you it is not so. Many of the points brought up are concerned either with the diagnosis of patent ductus arteriosus or with the estimation of the severity of the disturbance of circulation associated with it. Judgment on both is much aided by the appropriate use of the radiologic evidence. The situation is something like this: A certain number of patients with patent ductus arteriosus die of subacute bacterial endarteritis. In general, these patients would not have this disease in the absence of patency of the ductus. There is therefore some reasonable ground for the hope that if the ligation of the ductus actually leads to a restoration of the integrity of the local structure the incidence of subacute bacterial endarteritis may be reduced. Only the passage of time and the observation of many patients will answer this question. Patients with patent ductus arteriosus take not only the risk of subacute bacterial endarteritis but also, although we do not know how frequently, the danger of heart failure or of long continued mild cardiac disability. The ingenious and successful operation devised by Dr. Gross has had one far reaching effect that no one has mentioned: it has stimulated enormously the interest in studying the problems of patent ductus arteriosus and of congenital heart disease in general. Two or three speakers have suggested today that there is a possibility that ligation of the ductus may be inadvisable in certain cases because such ligation may interfere with a compensatory function of the ductus. That is, it is suggested that the ductus arteriosus may in some cases play a useful role and permit the passage of blood essential for life. When the patent ductus is playing a useful role the lesions are such that the patient is cyanotic. Therefore, in the absence of cyanosis one need not be concerned lest ligation of the ductus abolish a useful function. Two final points: First, to emphasize again the originality displayed by Dr. Gross in his contribution. It has not only meant a lot to the lives of his patients but is going to mean a great deal to the knowledge of heart disease. Second, to thank the Section on Radiology for giving an opportunity to a group of men and women interested in heart disease to discuss these problems of such interest to themselves in this pleasant and instructive environment.

PREGNANDIOL EXCRETION FOLLOWING
BILATERAL OOPHORECTOMY IN
EARLY PREGNANCY

GEORGEANNA EMORY SEEGAR, M.D.

AND

ELEANOR DELFS, M.D.

BALTIMORE

Browne and Venning¹ first suggested that the excretion of pregnandiol could be used as a measure of progesterone production and therefore of corpus luteum function. Because the pregnandiol excretion increased markedly during pregnancy and disappeared completely at parturition, it was suggested that progesterone might be produced by the placenta after the second month of pregnancy. Browne and Venning¹ and Jones and Weil² have reported cases in which the corpus luteum of pregnancy was removed on the one hundred and twentieth and the fifty-fourth days, respectively, and the pregnandiol excretion subsequently remained within normal limits. These cases seem to lend additional support to the theory of a placental origin for progesterone during pregnancy. However, in both cases functional ovarian tissue remained.

It has recently been possible to study the pregnandiol excretion throughout pregnancy of a woman from whom all ovarian tissue was removed on the sixty-third day of gestation. Clinically this patient presented no abnormalities during pregnancy and parturition but the pregnandiol excretion never rose above the level usually found during the first ninety days; e. g., values comparable to those found during the luteal phase of nonpregnant cyclic women. Cyonin,³ chorionic gonadotropic, assays were within the range of those found in normal pregnancies. These data are presented in the accompanying chart together with pregnandiol determinations performed in this laboratory on normal pregnant women for purposes of comparison.

METHODS

The pregnandiol determinations were performed by the technic of Venning,⁴ with several minor modifications designed to eliminate errors arising from the spontaneous hydrolysis of the pregnandiol complex to free pregnandiol. Collections were made into bottles containing 200 cc. of normal butyl alcohol each, the bottle being shaken well after the addition of each voided amount. Since hydrolysis of the glucuronide is negligible in butyl alcohol, most of the pregnandiol remains in the combined form. Any free pregnandiol which may have appeared during collection and extraction was recovered from the acetone solutions by a method described by Weil⁵ and by Geschickter and Bucher.⁶ The amount of free pregnandiol was then added to the calculated amount obtained in the combined form to give the total pregnandiol.

Assays of chorionic gonadotropin were performed on serum and urine by a method to be published.⁷

REPORT OF CASE

M. W., a Negro woman aged 26 who had had four full term spontaneous deliveries, was admitted to the hospital Sept. 12, 1939. Her past history was negative except that on May 29, 1939, she had had a left salpingo-oophorectomy performed because of chronic salpingitis and a cystic ovary. On admission she complained of slight intermittent vaginal bleeding during the preceding two weeks and severe pain in the lower part of the abdomen of two days' duration. Her menstrual history revealed that she had had only one menstrual period since her operation in May, the date of that period being July 2. Vaginal examination showed the cervix to be softened, the uterus somewhat enlarged and a tender cystic mass in the right fornix. A tentative diagnosis of ectopic pregnancy was made and an exploratory laparotomy was performed immediately, September 13. At operation the mass was found to be an ovarian cyst, and a right salpingo-oophorectomy was carried out. The uterus was noted to be enlarged and softened, giving the appearance of a uterus of early pregnancy. A Friedman test, performed on the day of operation, was reported to be negative. A twenty-

A comparison of the pregnandiol values in milligrams per twenty-four hours in a case of pregnancy in which no ovarian tissue was present and values obtained on normal pregnancies during the same period. The normal range for pregnandiol during pregnancy, as obtained by Venning,¹¹ is also shown.

four hour specimen of urine, collected September 14, sixty-three days after her last menstrual period, showed no pregnandiol. The patient made an uneventful recovery and left the hospital September 24.

She returned to the dispensary November 1, at which time the uterus was found to be the size of a sixteen weeks pregnancy and the fetal heart was audible. She was admitted to the ward for study on November 11. A quantitative assay of serum gonadotropin showed 12,700 international units per liter and the urinary gonadotropin assay was read at 5,400 international units per liter. The twenty-four hour pregnandiol values at this time, on her 132d day of gestation, showed 3.4 mg. November 12, 11.8 mg. November 13 and 9.6 mg. November 14.

The remainder of the patient's antepartum course was normal in every respect, her only complaints being occasional hot flushes and slight abdominal pain. Blood pressure readings remained at about 124 systolic and 70 diastolic throughout her entire pregnancy. She had no vomiting, edema, headaches or visual disturbances. Her urine showed no albumin, casts or red blood cells. Pregnanediol determinations made at monthly intervals showed 8.6 mg. December 10, the 161st day of gestation,

7. Delfs, Eleanor, to be published.

21.3 mg. Jan. 9, 1940, the 191st day, 12.6 mg. January 17, the 199th day, and 18.4 mg. February 22, the 244th day.

A serum gonadotropin assay taken on March 6, 1940, showed 8,100 international units per liter.

Labor occurred spontaneously on March 26, fourteen days before the expected date of confinement. A normal female child was delivered by breech extraction and has since done well. The placenta delivered without difficulty. Grossly it was not remarkable. The weight was 515 Gm. and the dimensions were 18 by 18 by 2 cm. There were several subchorionic infarcts; the maternal surface was normal.

COMMENT

Strong support is lent to the theory that the corpus luteum hormone has an extra-ovarian source during the last two thirds of gestation by the fact that the patient continued to excrete pregnandiol in the urine during the last seven months of pregnancy following the removal of all ovarian tissue. The placenta seems to be the most probable source of the pregnandiol, although a different origin might be argued under these circumstances, as Beall and Reichstein⁸ have isolated progesterone and allopregnanolone from adrenal extracts. Venning, Weil and Browne⁹ have reported the presence of pregnandiol in the urine of two patients with an adrenogenital syndrome neither of whom had corpora lutea; Engel¹⁰ has recovered small amounts of pregnandiol from large volumes of male urine.

The significance of the unusually low levels of pregnandiol cannot at present be evaluated. It is improbable that the determinations entailed a loss of the substance for, as shown in the chart, results in normal cases obtained at the same time approximate those given by Venning¹¹ for normal pregnancies. The presence of some obscure abnormality of the liver or kidney function of this patient which might interfere with the conjugatory or excretory mechanism of the pregnandiol complex is a possibility which must be considered. At present it is possible only to state that there were no demonstrable abnormalities in these systems. The placenta was of normal size and was producing normal amounts of chorionic gonadotropin.

Several theoretical possibilities remain. The first of these is that the ovary may be the main source of progesterone throughout pregnancy, the placenta producing only small supplementary amounts. This has generally been thought unlikely, on the basis of histologic evidence, as the regression of the corpus luteum, as judged by the microscopic appearance, begins at about the third month of pregnancy; that is, at a time when the pregnandiol level is beginning to rise. It cannot be denied, however, that a recognizable corpus luteum may persist throughout gestation.

A second possibility, for which there is no evidence at present, is that the ovary, although not the source, is at least concerned in the metabolism of progesterone during late pregnancy. Lastly, when a sufficient number of cases have been studied it may be found that the values obtained are not beyond the range of uncomplicated gestation. Browne¹² has found several cases with

levels ranging from 10 to 15 mg. of pregnandiol at about the 130th day of gestation and feels that, although the values presented here are certainly low for normal pregnancy, they are not impossible.

In the case presented all ovarian tissue was removed on the sixty-third day of pregnancy. Clinically no abnormalities were observed during pregnancy or parturition. The excretion of pregnandiol, however, remained far below that found in a normal pregnancy; on only two occasions did it even slightly exceed values found in nonpregnant cyclic women. Cyonin, chorionic gonadotropin, determinations on blood and urine gave values comparable to those found in normal pregnancies.

DERRIS ROOT DERMATITIS

MAURICE DORNE, M.D.

AND

TOWNSEND B. FRIEDMAN, M.D.

CHICAGO

Derris root or its extractives have been available in the United States for many years. In September 1911 the McDougalls applied for the first United States patent for its use as an ingredient for animal washes, insecticides and vermifuges.¹ The first reference to this root as an allergen was made by Westen² in 1937, when he reported improvement in two cases of bronchial asthma from exclusion of this substance from the environment. The sole reference revealed by a careful survey of the literature to derris as a cause of dermatitis was that of Racouchot³ in 1939. Haag⁴ states that he has on several occasions had inquiries about workers with derris who had contracted cutaneous lesions, but in none of these was the specific nature of the eruption given. From the information he received he was unable to ascertain the exact nature of the eruption.

REPORT OF CASE

F. K., a white man aged 27, married, was referred to one of us (M. D.) by Dr. D. R. McLean Dec. 12, 1939. For the past eight years he had worked as a florist's helper spraying insecticides on plants, cutting and bunching flowers and potting plants. He handled about forty different varieties of plants including chrysanthemums, pom-poms, lilies, hyacinths and tulips. November 20 he cut the palm of his right hand with a piece of glass. He applied iodine and covered the cut with adhesive tape. November 21 there developed an intense itching involving the legs, thighs, arms, forearms and genitals. There was some redness present in these regions but no other visible cutaneous lesions. He did nothing for the condition. He had been spraying flowers and plants for several days previously, and during the process his clothes became soaked with the spray. November 23 the penis began to swell. He went to a drug store, where the clerk sold him a bottle of a proprietary lotion, which he applied to his entire body and which soothed the skin. He also took some sodium bicarbonate baths. The following day he had a recurrence of the intense itching and he consulted a physician, who gave him a lotion (calamine). The itching was temporarily relieved by the application of the lotion and an ice bag. November 28 the itching was again very intense and the genitals became greatly swollen. He was hospitalized by the physician for five days, during which period the itching was greatly relieved. When first seen by one of us the patient stated that the itching was intermittent, occurring at irregular intervals during the day and night. It was also ascertained that five years previously he had a primrose dermatitis. The

patient's family history for allergy was negative. He stated that he had never had any other disease of the skin.

Examination December 12 revealed a number of discrete follicular papules and pustules on the thighs, legs and popliteal spaces and over the sacrum. There was a patch of erythema in each cubital fossa. There was marked dermatographism. These features suggested the possible allergic nature of the dermatitis. The history suggested insecticides as the possible cause. To identify the cause, further study was undertaken.

Patch tests were performed with the substances which the patient handled.

After forty-eight hours the patches were removed and revealed no reactions. Subsequently, allergic investigation was undertaken (T. B. F.) and tests to derris and pyrethrum by the scratch technic gave negative results. Intracutaneous tests elicited a marked reaction to a 1:1,000 solution of derris extract. Passive transfer tests were performed, and circulating antibodies were demonstrated in three different subjects who gave no reaction in their control sites.

On complete avoidance of contact with insecticides containing derris, the patient has made an uneventful recovery and has remained free from symptoms although working at his occupation to date (March 1940).

HISTORICAL SURVEY

The roots, bark and shrubs of the *Lonchocarpus* family originally came from the Malay Peninsula but are now cultivated in large amounts in Brazil and Peru. This family of plants has served the natives of the Malay Islands and those of the Amazon region since

Results of Patch Tests with Substances Handled by the Patient

		24 Hrs.	48 Hrs.
1. Hitox	1: 600 in water	0	0
2. Loro	1: 600 in water	0	0
3. Multicide	1: 600 in water	0	0
4. Derrisol	1: 600 in water	0	0
5. Chrysanthemum, leaf and petal.....		0	0
6. Pom-pom, leaf and petal.....		0	0

Substances 1 to 4 are insecticides. Their ingredients are as follows:

Hitox: rotenone, pyrethrum, vegetable oil.

Loro: aliphatic thiocyanates, principally lanryl, 50%; thiocyanate sulfur, 5.75%; aliphatic sulfonates, 40% (combined sulfur 0.4%); inert ingredients 10%.

Multicide: water, 14%; pyrethrum extractive, 18%.

Derrisol: derris resin, 5%; fatty acids, 50%; inert matter, 45%.

ancient times. The natives apparently knew of its lethal powers for a much longer period than that of curare and used it to make a poison for arrows. The animals struck would die in a few minutes, but their flesh would remain edible because practically none of the poison is assimilated by the digestive tract. The natives have also used this poisonous root to catch fish. The poison is a fish toxin of almost unbelievable power—a dilution up to 300,000 serves to anesthetize and kill a quantity of large fish in a few minutes. The fact is more surprising since the ichthyotoxic principle of derris is only slightly soluble in water.

The farmers of China, Java and Ceylon were apparently the first to recognize the remarkable insecticidal properties of the rotenone-containing plants and use the poison extensively in their horticulture. The use of these insecticidal plants in modern agriculture has spread rapidly because they are not as toxic to man or animals as are the insecticides containing arsenic, lead and copper.

BOTANY

Roark⁵ deals fully with the botany of derris and allied plants in his monograph on *Lonchocarpus*, which

is a genus of tropical shrubs comprising some sixty species. However, only four known species and three suspected species have insecticidal properties. The two most commonly employed commercially are cubé root (*Lonchocarpus nicou*) and derris root (*Derris elliptica*).

TOXICOLOGY

Studies have been reported by Ambrose and Haag⁶ on the chronic toxicity of derris (*Derris elliptica*) for rabbits, dogs and rats. Rabbits given 60 mg. per kilogram and more showed signs of cumulative toxicity. In adult dogs on a diet containing 0.04 per cent of derris, no symptoms of toxicity were observed. In young growing dogs on the same diet, the most pronounced effect was the stunting of growth. Diets containing less than 0.0312 per cent of derris had no demonstrable effect on the growth of rats. As the concentration of derris in the diet was increased, the inhibition in growth was more marked. Pathologic studies of the tissues of dogs and rats indicated that derris, in all concentrations studied, was somewhat injurious, the liver being the only organ consistently affected.

Haag⁷ was so convinced of the harmlessness of rotenone that he took 150 mg. by mouth without experiencing any harmful effects.

SOURCES OF CONTACT

In view of the fact that the plants of the derris family are now being cultivated in the American countries and because of their superior insecticidal properties and apparent absence of toxicity when ingested by human beings, they are rapidly replacing the arsenical and mercurial insecticides. A number of insecticides, animal washes and vermifuges containing derris root or its extractives are now available in the American markets.

COMMENT

Racouchot³ reported a series of cases of dermatitis occurring in workers who ground the dry derris root into a powder which was used as an insecticide. The workers handling the powder presented in two or three days a violent dermatitis of the genital region. The scrotum became reddish violet and markedly edematous, and the natural folds became exaggerated. The skin of the penis and prepuce was erythematous and cut with shallow fissures. The pruritus was intense. After forty-eight hours, when contact with the powder was avoided, the irritated skin desquamated in large and small plaques, and all conditions returned to normal. If the noxious contact was continued, the dermatitis became aggravated but did not extend farther than the genitocrural fold. The pruritus was intensified and the erythema increased. The skin was covered with large, flat papules *en pastille* about 0.5 cm. in diameter, excoriated and weeping. The prepuce was edematous and weeping. The dermatitis returned with each new exposure. All the cutaneous reactions (patch tests?) were negative and the skin of the genital region alone was affected. He thought this was due to the fineness of the skin and to the constant humidity and oiliness of this location. The active principles of cubé are, in fact, much more soluble in oily mediums than in water. He instituted prophylaxis in the grindery with excellent

6. Ambrose, A. M., and Haag, H. B.: *Indust. & Engin. Chem.* **30**: 592 (May) 1938.

5. Roark, R. C.: *Bulletin E-367*, U. S. Department of Agriculture, Bureau of Entomology and Plant Quarantine, 1936.

7. Haag, H. B.: *J. Pharmacol. & Exper. Therap.* **43**: 193 (Sept.) 1931.

results. A closed ventilating system was installed and the grinders were modernized. Each worker received a gas mask of the small type to cover the mouth and nose. This type of mask is sufficient because the derris dust apparently did not cause conjunctivitis. He placed in each mask a moistened marine sponge about 2 cm. thick, which served very well to stop the powder. Other symptoms that he noted were irritation of the mucosa and an ulcerative, scabby rhinitis with a transient but complete anosmia. In a few instances it irritated the lips like a pigment, as well as the tongue, and produced in it anesthesia followed by a very disagreeable and severe pain. With the mask these sense organs recovered their functions. There has not been a single case of laryngeal or pulmonary complication. A guinea pig has lived for six months in the pure powder at the site of the grinders without being made ill. Each worker is furnished with a special closure for his fly and about the ankles. With these precautions and with the proper body care, he observed no further accidents.

Our patient when seen presented a residual dermatitis but gave a history of a symptom complex involving chiefly the genitalia analogous to that described by Racouchot.

We feel that our case is not a contact dermatitis, but rather a true allergic dermatitis. It is our interpretation that the cases described by Racouchot are of the same type, since the workers were able to resume their regular occupation without recurrences when protected by gas masks and working in modernized and properly ventilated rooms.

SUMMARY AND CONCLUSIONS

1. A case of dermatitis was due either to the inhalation of an insecticide containing derris extractives or to absorption through lacerated skin.
2. There are various sources of possible contact with derris, a plant of the Lonchocarpus family.
3. It was shown that this substance is not a primary cutaneous irritant in the dilutions ordinarily employed.
4. It was shown by negative patch tests that this substance is not a contact irritant.
5. This substance produces dermatitis by a true antigen-antibody reaction, as indicated by positive intracutaneous tests and by positive passive transfer reaction.
6. Avoidance of exposure appears to be the method of prevention for sensitive individuals.
7. Dermatitis is apparently rare in spite of the widespread use of derris.

104 South Michigan Avenue.

Disease and Illness.—Disease is only one element of illness and is not the only cause of disturbances of the activities and functions of the body. There is in fact no fixed relationship between disease and illness. Disease does not necessarily cause illness, and illness may exist without disease. Free and efficient living is dependent on the conditions under which a person lives as well as on his physical state. Just as an automobile may run perfectly along a smooth and level road but give out unexpectedly on a hill, so illness may be precipitated by the burden an individual is forced to carry, placed on him by the conditions of his work, by the people who surround him or by the circumstances of his existence. Illness results from disturbed bodily functions, and its character, duration and severity are dependent not alone on the physical causes of these disturbances but also on the characteristics of the patient as an individual and on the total situation of which he is the center.—Robinson, G. Canby: *The Patient as a Person*, New York, Commonwealth Fund, 1939.

Clinical Notes, Suggestions and New Instruments

SUBACUTE STREPTOCOCCUS VIRIDANS ENDARTERITIS COMPLICATING PATENT DUCTUS ARTERIOSUS RECOVERY FOLLOWING SURGICAL TREATMENT

ARTHUR S. W. TOUROFF, M.D., AND HARRY VESELL, M.D.
NEW YORK

The two serious complications of patent ductus arteriosus that occur most commonly are (1) cardiac failure due to the alteration of circulatory dynamics and (2) subacute bacterial endarteritis resulting from implantation of organisms at the site of the congenital abnormality. Gross,¹ in an attempt to correct circulatory abnormality and in the hope of preventing the future development of subacute bacterial endarteritis, was the first successfully to ligate a patent ductus. Since the report of this case in February 1939, Gross and Hubbard² have recorded eight additional operative cases and Bullock, Jones and Dolley³ a series of eleven. The results in these twenty cases have demonstrated conclusively that ligation of the patent ductus is effective in correcting circulatory abnormality.

Up to the present, subacute bacterial endarteritis complicating patent ductus has been treated by medical methods identical with those employed in cases of subacute bacterial endocarditis. It may be stated that such treatment in general has been unsuccessful. In May 1938, Graybiel, Strieder and Boyer⁴ reported a case in which an attempt at cure was made by surgery. Because of technical difficulties, their plan of ligating the patent ductus could not be carried out and the structure was pliated by external sutures in an effort to obliterate the lumen. The patient died on the fourth postoperative day of acute gastric dilatation, and at postmortem examination the ductus was found to have been incompletely occluded. Aside from this report we have found no record of any attempt at cure of the infection by surgical methods. Our purpose in this communication is to report a case of patent ductus arteriosus complicated by subacute Streptococcus viridans endarteritis in which recovery apparently has followed operation. To the best of our knowledge, this is the first such case to be recorded in the literature.

REPORT OF CASE

History.—S. S., a native born white woman aged 29, single and an office worker, was admitted to the medical service of Beth Israel Hospital, Jan. 20, 1940. The patient was one of five siblings, none of whom suffered from any known congenital anomaly. She had been told that a cardiac murmur had been present since birth but that she had not been a "blue baby." During her childhood, although she was warned against engaging in strenuous games, she skated, swam and played ball. She was able to do these things without manifesting unusual distress or shortness of breath. At the age of 8 she underwent a tonsillectomy. At the age of 14 she suffered a mild attack of typhoid. Since then she had been quite well until the onset of the present illness.

About two and one-half months prior to admission to the hospital she became nervous, irritable and easily fatigued. These symptoms were progressive and she soon lost her appetite and she began to vomit and to lose weight. Although she did not take her temperature, she "felt warm" and perspired freely on a number of occasions. Two weeks before admission a non-productive cough developed. One week later, and again on the day of admission, she had a chill. During the illness, the weight fell from 95 to 88 pounds (43 to 40 Kg.).

Examination.—The patient was pale, thin and underdeveloped. She was acutely ill. The temperature was 103.4 F., pulse rate 144 and respiratory rate 18. There was no dyspnea or cyanosis. No petechiae were present in the fundi or conjunctivas nor on the body or extremities. The pharynx was not injected, the teeth were in good repair and cervical lymph glands were not palpable. The main features of interest were found on examination of the heart. The latter was not enlarged. The point of maximal apical impulse was situated in the fifth interspace in the midclavicular line. A short, blowing systolic murmur was heard over the apex and over most of the left precordium. In the second interspace, immediately to the left of the sternum, a moderately loud machinery-like murmur replaced the first sound. This murmur continued through the second sound and apparently through most of diastole. It also could be heard in the first and third left interspaces, immediately outside the apex and between the mesial border of the left scapula and the vertebral column. The pulmonic second sound was accentuated. Over the aortic area the sounds were normal. There was no evidence of cardiac failure.

The lungs were clear; the spleen was barely palpable. There was no clubbing of the fingers. The blood pressure was 98 systolic, 60 diastolic, and on the five succeeding days 94/66, 110/66, 110/72, 110/70 and 108/68.

Laboratory Data.—A teleroentgenogram revealed the heart to be of normal size but somewhat oval. There was some prominence of the arc of the pulmonary artery and left auricle,

unsuccessful. Accordingly, surgical therapy was considered and seemed warranted for various reasons. It was postulated that if the vegetations were confined to the ductus, excision of the latter might result in recovery. If the vegetations were situated in the ductus, pulmonary artery and right side of the heart, it was hoped that excision or ligation of the ductus would promote healing of the lesions by eliminating the arterio-venous communication and the swirling current of blood. It was further suggested by Dr. Emanuel Libman, who saw the patient in consultation, that the shutting off of the flow of oxygenated blood from the aorta into the pulmonary artery might render conditions less favorable for the growth of vegetations in the pulmonary artery and right side of the heart.

It was realized that operation presented certain dangers such as infection of the pleura and mediastinum, accidental hemorrhage from the friable infected ductus and dislodgment of infected thrombi into the circulation. However, in view of the otherwise almost hopeless prognosis, it appeared warranted to take these risks. With the understanding, on the part of the patient's relatives, that the procedure was experimental, but under the circumstances worthy of trial, operation was undertaken seven days after admission.

Operation.—On Jan. 27, 1940, an operation was performed (by A. S. W. T.) under intratracheal cyclopropane anesthesia. A left-sided anterior thoracic incision was made, from the sternum to the anterior axillary line in the third intercostal space. The second and third costal cartilages were divided

Patient's temperature course in hospital. B. C. indicates blood culture; S1, sulfapyridine; S2, sulfapyridine stopped; P. I., pulmonary infarction.

with straightening of the left cardiac border. Moderate pulmonary vascular congestion was present. Kymographic examination indicated very marked pulsation of the pulmonary artery. The four lead electrocardiogram was normal; left axis deviation was present. A phonocardiogram revealed the murmur over the pulmonic area to be continuous through systole and diastole, except for a short period of silence during pre-systole. The specific gravity of the urine ranged up to 1.020. Albumin and dextrose were absent. An occasional red blood cell was seen in the low power field. The benzidine test was repeatedly negative. No casts were found. The blood contained 3,850,000 red cells per cubic millimeter. Hemoglobin content was 74 per cent. There were 17,500 white cells, of which 69 per cent were polymorphonuclear leukocytes and 31 per cent mononuclear cells. The erythrocyte sedimentation rate was 45 mm. in forty-five minutes. The Wassermann, Kline and Kahn tests gave negative results. A blood culture taken two days after admission revealed 50 colonies of *Streptococcus viridans* per cubic centimeter after twenty-four hours incubation and 400 colonies per cubic centimeter after forty-eight hours. Another blood culture taken two days later yielded heavily positive results in the flasks but plates were not inoculated. The diagnosis of patent ductus arteriosus with complicating subacute *Streptococcus viridans* endarteritis was made.

The patient was observed for seven days, during which time the clinical course was of the septic type, with sweats and irregular fever ranging between 99 and 103.4 F. During this period the only medication administered was acetylsalicylic acid and phenobarbital.

In the past at our institution attempts to cure subacute bacterial endocarditis by means of drugs or hyperthermia had been

and the pleural cavity was entered. By retracting the divided ribs upward and permitting the lung to collapse, an excellent exposure of the aortic arch and the left pulmonary pedicle was obtained. An extensive tremor and thrill were noted over the exposed surface of the heart. The thrill also was palpable over the root of the aorta and the region of the pulmonary artery. Through a directly applied sterile stethoscope a very loud, harsh, whirring murmur could be heard over these areas throughout the cardiac cycle. A 4 cm. incision was made in the mediastinal pleura below the aortic arch, and the under surface of the arch, ductus arteriosus and pulmonary artery were freely exposed. The ductus measured about 14 mm. in length and 10 mm. in diameter; the pulmonary artery was markedly dilated. The thrill and murmur previously described were now detected directly over these two structures. The left recurrent laryngeal nerve was identified as it passed beneath the junction of the ductus and aorta. The ductus next was isolated, except on its deep surface, where it was quite adherent. With some difficulty the deep surface was freed, and a strand of heavy silk on a ligature carrier passed beneath it. As gentle upward traction was made on the untied ligature, vigorous and profuse bleeding suddenly began from the depths. Although the source of the hemorrhage was not visible, it was assumed to be due to a tear in the deep surface of the ductus. In view of the fact that only the gentlest traction had been made, it was further assumed that the wall of the ductus was very friable. With difficulty, bleeding was temporarily controlled by pressure, and clamps were applied to the ductus. The structure then was rapidly dissected free and divided completely. The upper end was ligated with a heavy silk ligature immediately adjacent to the aorta and the lower end similarly ligated adjacent to the

pulmonary artery. Because of assumed contamination of the operative field from the divided ductus, the incision in the mediastinal pleura was not sutured. Immediately before the thoracic closure was completed the lung was expanded with positive pressure.

Concomitant with the severe hemorrhage during operation, the blood pressure and pulse became almost imperceptible and the patient went into shock. After an immediate intravenous infusion of acacia, followed by a transfusion of 500 cc. of citrated blood, improvement was noted, but her condition was still precarious at the end of the operation.

Postoperative Course.—On her return to the ward two transfusions of 500 cc. each were administered within a period of several hours. Within another few hours evidence of shock had disappeared. During the first few days intranasal oxygen was administered at intervals to control transient episodes of dyspnea and cyanosis. Several hundred cubic centimeters of serosanguineous fluid was aspirated from the left side of the chest on the third, fourth and ninth postoperative days. Cultures of these fluids subsequently were reported negative. On the second postoperative day the temperature rose to 104.4 F. but thereafter receded, except for transient rises, to 103.4 F. and 103 F., on the fourth and ninth postoperative days respectively, concomitant with minor episodes of right-sided pulmonary infarction. From the tenth to the eighteenth day after operation, the temperature did not rise above 100 F. From the nineteenth to the twenty-sixth day, when the patient was discharged from the hospital, the temperature gradually returned to normal. The wound healed by primary union, all sutures being removed on the fifth postoperative day. The patient was allowed out of bed on the twelfth day after operation.

Six postoperative blood cultures were taken (on the second, fourth, seventh, twelfth, sixteenth and twenty-first days respectively) and all remained sterile throughout fourteen days of incubation. Some of these blood specimens were arterial as well as venous; some were anaerobic as well as aerobic.

It was planned to withhold chemotherapy following operation in order to observe the effect of surgery alone on the bacteremia. However, because of fear of the development of mediastinal and pleural infection, sulfapyridine was administered on the afternoon of the fifth postoperative day. Six Gm. of the drug was given on that day, and 3 Gm. on the following day, at which time it was discontinued because of persistent vomiting. It is to be noted that when the administration of sulfapyridine was begun the temperature was subsiding and was down to 100 F. and that the two postoperative blood cultures taken up to that time had been reported sterile. It therefore appears highly unlikely that the drug had any significant effect on the bacterial infection. When the patient was discharged from the hospital on the twenty-sixth postoperative day, she was symptom free, had gained 3 pounds (1,360 Gm.) and appeared in good physical condition. At that time she was referred to a convalescent home with instructions to return to the hospital in three weeks.

During a twenty-two day stay in the country, the temperature, taken daily, remained normal; she gained 7 pounds (3,175 Gm.) and felt entirely well. She was readmitted to the hospital forty-eight days after operation for a check-up investigation. During a three day period of observation in the hospital the rectal temperature, taken twice daily, was 98.6 F. on each registration. The blood pressure was 110/70, which was essentially the same as before operation. Of great interest was the persistency of the continuous murmur⁵ over the pulmonic area. Its intensity had diminished somewhat, however, and it was more circumscribed than it had been previously. The spleen no longer was palpable. Slight hoarseness due to partial loss of function of the left vocal cord was present. The urine was normal. No red cells were observed and the benzidine test gave negative results. The blood count was normal. The hemoglobin content was 102 per cent. The sedimentation rate

was 5 mm. in forty-five minutes. A blood culture revealed no growth. The four lead electrocardiogram was identical with the one taken before operation. On the basis of the observations, the assumption that bacterial infection still was absent was warranted. Accordingly, the patient was discharged and permitted to return to work. When last examined on March 30, 1940, exactly nine weeks after operation, she appeared in excellent health.

SUMMARY

A woman aged 29 had patent ductus arteriosus with superimposed subacute *Streptococcus viridans* endarteritis. During a seven day period of hospital observation the clinical course appeared severe. Blood cultures revealed as many as 400 colonies of *Streptococcus viridans* per cubic centimeter. Operation was performed primarily in the hope of eliminating the infection. The procedure consisted of division and double ligation of the ductus. Severe hemorrhage occurred at operation, but the postoperative course otherwise was essentially uneventful. Nine weeks has elapsed since operation.⁶ All postoperative blood cultures, seven in number, have been sterile. This is the first successful ligation of a patent ductus arteriosus complicated by subacute bacterial endarteritis to be reported. It is also the first such case in which recovery from the bacterial infection apparently has resulted.⁷

THE DRAMA OF TUBERCULOSIS

CLINICAL LECTURE AT NEW YORK SESSION

JAMES ALEXANDER MILLER, M.D.

NEW YORK

THE HUMAN DRAMA

The effect of long drawn out chronic illness on life and character is well known to physicians and has appealed to historians, dramatists and story tellers in many lands, through various tongues and in numerous forms.

Many are the famous personages in various walks of life whose careers have been influenced by personal experience with tuberculosis. To enumerate only a few we may note:

In literature, Schiller, Keats, Byron, Thoreau, Brontë, Elizabeth Barrett Browning, Robert Louis Stevenson and Eugene O'Neill.

In music, Chopin, Paganini, Mozart and von Weber.

In art, Raphael, Molière and Rachel.

In philosophy, Voltaire, St. Francis of Assisi and John Calvin.

Among statesmen, Cicero, Cecil Rhodes and Kerensky.

Among military leaders, Lord Nelson and John Paul Jones.

In science, Descartes, Priestley and Luther Burbank.

In medicine, Laënnec, Ehrlich, Benjamin Rush and Trudeau.

Much has been written of the tuberculous temperament and many have accepted this suggestion as a definite fact with wide implications. Such a specific influence on temperament is extremely doubtful. There

5. As the result of observations made during operation in this case, and subsequently in three similar cases, it appears that in adults suffering from patent ductus arteriosus complicated by subacute bacterial endarteritis the continuous murmur, although originating in part in the patent ductus, is generated principally in the dilated pulmonary artery. The details of the observations on which this statement is based will be published in a future communication.

6. Since this paper was submitted for publication another eleven weeks has elapsed. During the period of twenty weeks since operation, the patient has been kept under close observation and remains in excellent general physical condition and free of all evidence of infection.

7. Three additional cases of patent ductus arteriosus complicated by subacute bacterial endocarditis have come to operation. The results in these cases will be presented in a forthcoming issue of the *Journal of Thoracic Surgery*.

Read in the General Scientific Meetings at the Ninety-First Annual Session of the American Medical Association, New York, June 10, 1940.

can be little doubt that a long struggle with such a serious chronic disease had a profound influence on the character and career of those mentioned as well as of thousands of less favored folk. Success in overcoming such a physical handicap not only demands courage but it develops strength of character and increased confidence to meet the other problems of life.

Even in failure, fate may be conquered by the development of acquiescence and a philosophic calm which gives inspiration to all about one and thus enables the spirit to triumph not only over disease but over death itself.

Interpreted in this sense, tuberculosis has undoubtedly profoundly affected the lives and careers of many to their own betterment and to the great advantage of mankind.

The story of the lives of these and other great men and women is each a stirring drama with a universal appeal.

This has been widely recognized in many works of nonhistorical literature where art has served to dramatize more highly the human elements of struggle, of disappointment, of success or of tragedy. Of these none is more widely known and appreciated than Dumas's romantic play *La Dame aux camélias*, or *Camille*, the story of which has also been dramatized in opera by Puccini in *La Bohème*.

The dramatic appeal of tuberculosis is recognized as a general one, directed to the imagination and sympathies of all but especially to physicians who through the long history of our profession have witnessed the patience, the courage, the tragedy of many grim struggles and often the eventual triumph.

The human side of our professional contacts has enriched our experience, has strengthened our faith in human nature and has developed our spiritual as well as material resources to help others combat this disease.

THE MEDICAL DRAMA

Fascinating as is the human story of this age long disease, it is the story of the gradual development of our knowledge of it that is of especial interest and concern to a gathering of physicians such as this. I therefore will address myself to a brief review of that history. This too is a drama of intense professional as well as human interest.

Such a historical review has the endorsement of Sir William Osler, who once wrote: "By the historical method alone can many problems in medicine be approached profitably. For example, the student who dates his knowledge of tuberculosis from Koch may have a very correct but a very incomplete appreciation of the subject."

EARLY HISTORY

References to tuberculosis are recorded in Persia and Egypt as far back as 2000 B. C. but it is not until the time of Hippocrates, 450 B. C., that any important medical records are available. While Hippocrates made some very keen clinical observations, as in his clear picture of pneumothorax and his emphasis on the value of rest, of a milk diet and of climatic change in the treatment of pulmonary tuberculosis, his theory of its causation was the aspiration of mucus from the brain and he conceived of its pathology as tumors of the lung with a tendency to suppurate.

Hippocratic medicine extended from Greece to Rome, where Galen, 150 A. D., was the dominating figure.

His conception of the disease was that of ulceration rather than tumor formation and he thought that it was caused by the corrosive action of tissue fluids.

Galen's ideas prevailed for 1,600 years. They were preserved and practiced in very crude forms almost exclusively in the monasteries during those long dark ages.

In the seventeenth century came the revival of learning, in which medicine shared. The advance of medical knowledge came primarily from postmortem examinations long proscribed by religious opposition and the first leaders were in Holland, notably Sylvius and Boerhaave, and in England, Willis. Thus was gross pathologic anatomy first established as the fundamental basis of scientific medicine.

In the eighteenth century the possibility of the communicability of tuberculosis was first recognized in Spain and later in Naples, where the first quarantine against the disease was established. In physical diagnosis the first great step was taken in 1761 by Auenbrugger, who introduced percussion as a valuable method in the physical examination of the chest.

In 1790 Baillie in London after careful anatomic studies expressed his belief that tuberculosis and scrofula were the same disease, a fact hitherto disbelieved.

THE NINETEENTH CENTURY

The nineteenth century developed medical knowledge to an extent and at a tempo never before known. The earlier decades were dominated by France. Bayle in 1810 classified pulmonary tuberculosis so as to simplify greatly clinical thought and laid the foundation for the astounding contributions of Laënnec, who in a few brief years coordinated the pathologic and clinical concepts of tuberculosis, crystallized them into one of the great medical classics, *Traité de l'auscultation médiate et des maladies des poumons et du cœur*, published in 1819, which stands today as a work unexcelled for accuracy and clarity of description. Incidentally he invented the stethoscope, for which feat he is perhaps most widely known and then he tragically died at the age of 45 from the very disease which he was the first to understand adequately and to describe.

Following Laënnec, Louis carried on his great French tradition of careful physical examination of the chest and, in Vienna, Skoda added notable contributions in the 1830's.

In 1843 Sir James Clark in England reemphasized climatic treatment especially in the mild environment of Madeira and the Riviera.

It was at this time that pathologic histology first began to be studied because of the development of the microscope.

Virchow in Berlin led the way in these studies, and in 1847 he gave the first accurate histologic description of tuberculous lesions. Master as he was, he still clung to some of the old erroneous theories, for example that tubercle was caused by irritation and that tuberculosis and phthisis were distinct and separate entities. As late as 1866 one of Virchow's students, Niemeyer, uttered the famous dictum "The worst thing that can happen to a case of phthisis is to develop tuberculosis."

The center of progress then shifted back again to France through the remarkable researches of Villemin from 1862 to 1867. The name of this brilliant investigator has been extraordinarily neglected in the history of tuberculosis. By clinical investigation supported by

animal experimentation he strongly opposed the then accepted theory of a diathesis as the cause of the disease and came to the conclusion that it was due to an extraneous agent of a virus nature. He considered tuberculosis comparable to syphilis and glanders and that it was a zymotic disease which was communicable and he proved that this communicability was accentuated by overcrowding. As a result, he suggested measures of prevention by the improvement of environment and by protection from exposure to known sources of infection. Villemin was thus the logical forerunner of Robert Koch and the bacteriologic era.

THE BACTERIOLOGIC ERA

The revolutionary discoveries of Pasteur, begun in 1870, laid the foundations of bacteriology and led to the knowledge of the causation of tuberculosis as well as of many other infectious diseases. Thus was begun the astoundingly rapid development of modern medicine, i. e., within the lifetime of some of us here present. Pasteur himself did not investigate tuberculosis but it was inevitable that his ideas of bacterial infection should have immediately directed attention to tuberculosis because of the suggestive facts already established by the investigations and theories of Villemin. Laboratory studies were prosecuted feverishly under the exciting stimulus of the new knowledge but tuberculosis proved a more difficult problem than some other diseases and it was not until 1882 that Robert Koch announced his proved discovery of the tubercle bacillus as the cause of tuberculosis. It is interesting to note that within a few months of Koch's announcement Baumgarten and a few months later Aufrecht published the fact that they too had recognized the germ of tuberculosis and there can be no doubt that these investigators discovered the tubercle bacillus coincidentally with and independently of Koch. Koch, however, has always been credited with the discovery because of the priority of his publication and also because his announcement was made in a paper which was a masterpiece of scientific description and logical thought.

This paper, entitled *Die Aetiologie der Tuberculose* and published in the *Berliner klinische Wochenschrift* April 10, 1882, is another of the great classics of medical literature. It is to be noted that these discoveries were materially aided by the use of the staining qualities of the aniline dyes developed by the researches of Paul Ehrlich.

The cause being known, naturally thoughts and hopes turned to the discovery of a cure for tuberculosis and by none more energetically than by Koch himself. In 1890 he electrified the world by the discovery of tuberculin, his experiments leading him to the belief that in it might be a specific cure. The excitement was intense. Welch, who was then professor of pathology and bacteriology in New York, sent his promising young assistant Hermann M. Biggs to Berlin and he brought back to America the first supply of "Koch's lymph," as it was then called. Trudeau in his isolated makeshift laboratory at Saranac Lake caught the spirit and began his lifelong clinical and animal experiments with tuberculin. All over the world scientists, physicians and laymen alike were in a highly excited state of eager expectancy that the cure for the greatest cause of disease and death was at hand. Slowly came the disillusionment, and it is a sobering reflection on the dangers of premature optimism that now, fifty years later, in

spite of countless experiments and many collateral additions to our knowledge, a specific cure of tuberculosis still eludes us.

The discovery of tuberculin however had real value, for through it as well as by bacillus inoculations Koch developed our knowledge of the variation in tissue reactions between primary and secondary infections, the so-called Koch phenomenon, and particularly later through its use as a diagnostic test, as developed in 1907 by Pirquet and Calmette.

Toward the end of the century the value of sanatorium treatment for tuberculosis, which was first instituted by Brehmer in 1853 and later by Dettweiler in 1874, became more generally recognized and the first sanatorium in the country was founded by Trudeau at Saranac Lake in 1884.

In 1895 Roentgen's discovery of the x-rays marked the beginnings of what was to become the invaluable diagnostic agents which they are today, and in 1894 Forlanini's early clinical experimentation with artificial pneumothorax, which later revolutionized the treatment of many cases of pulmonary tuberculosis.

THE MODERN ERA

We have thus seen that important beginnings in our present knowledge were made toward the end of the nineteenth century, but the extension of our knowledge and its practical application was rapidly and generally developed only after 1900, so that we may properly designate the last forty years since the turn of the century as the modern era. During this time progress in general medicine and especially in tuberculosis has been breath taking in its rapidity. The astounding details of this part of the story are, however, so well known that it will be profitable to review only briefly the high lights of this period.

Von Behring had just postulated the concept that adult tuberculosis derived its origin from childhood infection and in 1912 Ranke built on this and the pathologic studies of Ghon his philosophical treatise on the pathogenesis of the disease outlining three stages, the primary affect, the dissemination phase and lastly the localization in individual organs, especially the lungs. This laid the basis for the modern concept of the endogenous origin of phthisis.

Early in the century Koch and Theobald Smith entered into their famous controversy concerning the distinctive variation between human and bovine bacilli, in which Smith proved his contention of their essential cultural and biologic differences. From these and other researches developed the program for the control of tuberculosis in cattle and the pasteurization of milk, the success of which has almost eliminated certain forms of tuberculosis in man, notably so-called surgical tuberculosis.

One of the notable achievements of this early twentieth century era was the organization of the anti-tuberculosis campaign of education and prevention. In this country under the scientific and medical leadership of such men as Biggs, Welch, Trudeau, Osler, Flick and Knopf this campaign was crystallized into the National Tuberculosis Association, which organized a combined medical, social and lay crusade which now has units in every community, with the far reaching effects with which we are all familiar.

One of the most important results was the emphasis placed on the institutional segregation of infectious

cases, with the rapid increase of sanatorium and hospital beds to nearly 100,000 in the United States.

As an infectious disease tuberculosis became a chief concern of public health authorities, who, aided and encouraged by nonofficial agencies, developed the sanitary control regulations as we know them today. Biggs was the leader in this field in New York City and later in the state of New York. It was in 1893 that he first enforced compulsory registration of tuberculosis, against the strong opposition of the medical profession of that day.

Early diagnosis was soon discovered to be all important for successful treatment and from the multitude of overrefined methods have emerged the history of exposure and of suspicious symptoms, together with the x-rays as the most important factors in early diagnosis, even superseding the value of physical signs.

In recent years mass examinations of groups of the population supposedly well have proved the great value of combined x-ray and tuberculin surveys for discovering early lesions especially in the young age groups.

Treatment of course was not neglected. The so-called hygienic dietetic regimen as best exemplified in sanatoriums has continued to be the fundamental basis of treatment, and here strict rest during the active stages with carefully regulated exercise during convalescence has proved to be a most important factor. Forced feeding and climate have become relatively less important.

The search for a specific cure has been relentlessly prosecuted both in the laboratory and in the clinical field. Serums and vaccines, special and often fantastic diets and chemotherapy applied by inhalations, by mouth and by intravenous routes have all failed, leaving behind a trail of disappointed hopes, of which the Friedman turtle serum fiasco is perhaps the most lamentable.

Calmette's BCG vaccine is a partial exception to the rule of failure, but even this has not yet proved to be of real value and at best is only a preventive and not a cure. In general it may be said that the recent success of chemotherapy in other fields has stimulated hopes for something similar in tuberculosis, but the time is not yet.

Chest surgery has advanced tremendously. Following on the general use of artificial pneumothorax, surgical methods to improve the results of the treatment of pulmonary tuberculosis have developed pneumolysis in the cutting of pleural adhesions, introduced by Jacobaeus in 1912, later phrenicectomy and especially thoracoplasty, first suggested by Brauer and Friedrich in 1909, and materially advanced to the position of a generally accepted procedure by the work of Sauerbruck and Wilms in 1913. At the present time about 40 per cent of all cases of pulmonary tuberculosis are being treated by some form of collapse therapy.

The combined action of all these measures of prevention and treatment, sanitary control, improvement of social and economic environment, education of the profession and the public, institutional segregation, earlier diagnosis and improved treatment has resulted in an astounding diminution in the incidence and the death rate from tuberculosis.

In 1900 the death rate from this disease in the United States was 202 per hundred thousand and in 1939 this had fallen to 47, or less than one fourth of the 1900 figure, and even more strikingly in New York City it has come down from 280 in 1900 to 50 in 1939, or less than one fifth of the previous total.

THE PRESENT SITUATION

The astonishing progress that has been made in the control of tuberculosis during the past forty years, as evidenced by the statistics just cited, has led to a widespread impression that the fight has been won and that the extermination of the disease is in sight. While this would appear more nearly a possibility than ever before in history, it is the part of wisdom that this be not taken for granted. Tuberculosis is still one of the major causes of death, especially in the younger age groups, and while it no longer holds the center of the stage in the drama of disease it nevertheless still plays a most important role. With the still very numerous foci of infection which exist, it would appear that under certain conditions the disease might easily begin to increase again. Certainly this might be expected if the precautions and methods learned should be relaxed because of satisfied complacency. In the present world crisis, for example, one may properly be concerned over the effect of postwar conditions. The experience of the last world war taught us how easily under conditions of privation, strain and undernourishment the tuberculosis morbidity and death rate can raise rapidly. Also with all of our accumulated knowledge there is still much that we lack which lends certain elements of uncertainty to the situation. As we possess no specific treatment, our methods must still be indirect with especial emphasis on prevention. This includes segregation of infectious cases, earlier diagnosis particularly through mass surveys and follow-up of contacts, with more adequate treatment of discovered cases before they become clinically active. The more widespread use of the x-rays is essential in this program.

It is to be noted that all of these methods are directed against the infection or against disease that it has already caused.

THE FACTOR OF RESISTANCE

There is another aspect of the problem sensed but still imperfectly understood. This is the defense mechanism in the human body against the infection. That this is a very real factor is evidenced by the facts now known that when exposed many escape infection and that of those known to be infected only a little over 1 per cent actually develop clinical disease. The wherefore of this is not definitely known but there are some intimations concerning it. It is well known for example that unfavorable environment predisposes to tuberculosis, which has long been recognized as a disease of the poor. Better opportunity for infection undoubtedly plays a role here, but that lowered resistance is also important seems evident. Natural or constitutional resistance is evidenced by the great variation in susceptibility in individuals, in families and in races. This applies to susceptibility to infection as well as to disease, as shown by the appreciable number of children who, though definitely exposed, fail to react to tuberculin. Natural resistance apparently can be enhanced through generations and possibly in some form it may be inherited.

Insufficient or unbalanced diets play their part. This has been attributed in the past to improper caloric food values, but the increase of knowledge concerning vitamins indicates that they may soon be recognized to be of at least as great importance. At present, however, we lack any precise knowledge of the particular vitamins which may influence resistance to chronic infections such as tuberculosis.

There is overwhelming evidence that a tuberculous infection successfully met changes the reaction of the body to subsequent infections and that this change means increased resistance. Such acquired resistance is only relative and may be overcome by large doses of infection or may be lowered by adverse environmental conditions. This resistance, acquired through many years or generations of exposure to repeated small infections, modifies the character of the disease and diminishes its prevalence.

What will be the epidemiologic consequences when an ever increasing proportion of uninfected persons as seen especially in rural areas are exposed to infection in later life under urban surroundings is still an open question. In other words, is it better to face the vicissitudes of life with a positive or a negative tuberculin reaction? Opinions differ, but the present trend in our campaign against exposure to disease is certainly tending to create a predominantly tuberculin negative population and at the same time the disease itself is diminishing. Theoretically, however, one cannot help but share the apprehension expressed by Bushnell many years ago that under certain favorable conditions this might conceivably lay the foundation for the return of tuberculosis as an acute epidemic disease. What is much needed is some criterion, not yet available, which might afford a basis for discrimination between good and bad risks under undue exposure to infection.

To those who believe in the great protective value of small doses of infection, a system of controlled vaccination appeals as the most satisfactory answer. Many animal and clinical experiments have been made in this field, of which Calmette's BCG is the outstanding example; but neither this preparation nor other experiments have as yet been proved to be of widespread usefulness.

The discussion of this problem has assumed considerable recent importance with regard to the hazards of tuberculosis to the medical and nursing professions, but practically it would appear that this danger has been greatly exaggerated. In the meantime for better or for worse we are rapidly increasing the proportion of "virgin soil" for tuberculosis among our general population.

CHEMICAL POSSIBILITIES

In recent years there has been a shift of research activity from the immunologic field to that of chemistry. The biologic characteristics of the tubercle bacillus are quite different from those of the streptococcus and the pneumococcus and among them apparently is an increased resistance to the destructive or inhibitive action of chemical substances introduced into the living body. The challenge in the direction of chemotherapy has, however, a great appeal and hopes for the future are not without a reasonable basis.

This necessarily cursory review of the story of tuberculosis reveals grounds for great satisfaction. Made possible by scientific research, guided by medical skill and strengthened by the social and economic forces released by a widespread diffusion of knowledge to the public, the struggle to overcome the "Great White Plague" has attained notable successes.

As already indicated, there still remains much to be done. What part is to be played by the medical profession in what we hope may be the concluding acts of the drama?

PRESENT MEDICAL RESPONSIBILITIES

Earlier Diagnosis.—X-ray examination is the cornerstone. The cases of pulmonary disease which may be considered really early can be discovered only by this means. When definite physical signs are present, the disease is usually already advanced. The history of suggestive symptoms is the indication for a prompt x-ray examination. Surveys by combined x-ray and tuberculin examinations for groups of apparently healthy people should have the active support and cooperation of physicians, but as individuals their chief responsibility is to concentrate especial attention in the most likely direction; this means on certain races, on certain economic groups and, for all classes, on the contacts with known cases.

The Better Practice of Preventive Medicine.—This includes not only the activities just enumerated but also a consistent effort to build up general health so that any later infection can be the better resisted. In this age of preventive medicine it is to be feared that many physicians still neglect its practice in favor of attention to the more insistent demands and the greater medical interest of frank cases of disease.

Cooperation with Public Health Authorities.—These authorities have the direct responsibility for the control of infectious diseases. They must work largely through physicians. If we as physicians assumed a greater individual responsibility to act as self constituted health officers for those patients under our care, the combined effect of private and public effort might well be irresistible.

Provision for Prompt and Adequate Treatment.—Strict bed rest is the most essential factor in the treatment of cases of active disease. In the really early cases the results are prompt and remarkable. Bed rest is applicable not only to cases in which there is fever but also to many afebrile cases in which other manifestations of activity are present. Change of climate, so long advocated, is definitely subordinate in importance to rest and in many active cases the journey involved in changing climate is absolutely contraindicated. Later, during the convalescent stage, a change to a more favorable climatic environment, especially for city cases, is of real value but should always be combined with proper medical supervision.

The proper regimen of a rest cure is always difficult in the home and often is impossible. Unless the home conditions can be made right or if the physician in charge is not experienced and interested in the numerous small but essential details involved, institutional care in hospital or sanatorium is necessary. Moreover, the educational and training value of the sanatorium regimen is very great not only at the time but also later when the patient goes out to face the problems of the return to normal life.

The various forms of collapse therapy have great value in properly selected cases. That so large a proportion of all cases, about 40 per cent, are now treated by these methods is, however, a reflection on the efficacy of our early diagnosis and treatment, for these cases are already advanced in the disease. Nevertheless, collapse therapy saves many lives otherwise doomed and, while it still presents many difficulties and problems, it represents the greatest major advance in the treatment of pulmonary tuberculosis of our generation.

Incidentally it has revived a surgical interest in tuberculosis which is valuable for the proper understanding and treatment of the nonpulmonary forms of the disease as well.

The vital importance of time must be emphasized in all forms of treatment as well as in diagnosis. In the latter the interval should be short between incidence and diagnosis; in the former it should be long, far longer than is frequently appreciated. Many an apparent cure has been ruined by a premature return to normal life.

All patients, however well they may appear, require a careful follow-up with periodic medical supervision for several years, which is essential if disappointing relapses are to be avoided.

While we as physicians are carrying out these generally accepted principles of treatment we should be receptive to the possibilities of a better and more specific form of treatment. Cautiousness in accepting any such cures is warranted by numerous bitter experiences and by our realization of the peculiar difficulties of the problem; nevertheless, both the hope and the possibility exist and when they are realized the wise physician will be the most eager to give the method a fair trial and also be the best judge of its efficacy.

Thus I bring to a conclusion this brief survey of our progress in the knowledge and measurable conquest of tuberculosis.

To physicians the story may well bring satisfaction in the achievements of the past but it also presents a challenge for the future. Scientists have pointed and will continue to point the way. Sanitarians and sociologists will largely apply the principles established. But on physicians has always rested the responsibility for meeting the actual problems at first hand and it is on their skill in diagnosis and treatment that continued success largely depends. It is my hope that the history of the way that we have come will throw some sidelights on our present knowledge and also point the way for future progress.

The problems of chronic illness may not be as dramatic as the sudden crises of acute disease, but from their very duration they more profoundly affect individual, family and community welfare.

Tuberculosis is still one of the most prevalent and important of these diseases. The physician who finds it worth his while to study it carefully will realize that, while there is still much that is not known, his effort to acquire and apply present knowledge will find him closely in touch with many other diseases and he will be led to study not only the lungs but also practically every organ of the body. He will meet personal and family problems which demand a human and psychologic approach. He will be brought to a realization of the importance of social and environmental conditions, the study of which will greatly broaden his horizon. Lastly he will appreciate that tuberculosis is a community problem which in importance even outweighs the interests of the individual and of the family.

Thus tuberculosis demands much of the physician. It is a challenge to our best effort. The degree to which we meet this challenge is a measure of our achievement as physicians and as citizens and will determine our ability to continue to play the leading role in this great drama.

133 East Sixty-Fourth Street.

Council on Industrial Health

MEDICAL SERVICE IN INDUSTRY

THE COUNCIL ON INDUSTRIAL HEALTH HAS APPROVED THIS ARTICLE AS ONE OF A SERIES ON MEDICAL SERVICE IN INDUSTRY WHICH WILL APPEAR FROM TIME TO TIME IN THE JOURNAL.

C. M. PETERSON, Secretary.

THE PLACE OF MEDICINE IN INDUSTRY

Industry's earliest medical need was for competent surgical treatment of injuries actually or likely to become compensable. For most employers this obligation remains the most important and often the only motive for providing medical service. Consequently this relationship is the sole point of contact with industry and industrial health methods for most physicians. Many factors tend constantly to modify this traditional concept of medicine's usefulness to industry. Society through occupational disease legislation demands that industry protect its employees not against accidents alone but against any harmful health experience associated with work as a cause. Experience in the safety movement turns the attention of employers to prevention as a cardinal principle for lowering the incidence of disability suffered by workmen whether through accident or disease, industrially induced or otherwise. This attitude is significant. It implies a gradual but steady reduction in the amount of required remedial service now provided by industrial medicine and surgery. In place of it the physician in industry will be asked to supply more and better preventive medicine, employing methods, equipment and special information now falling within the province of industrial hygiene.

VALUE TO THE EMPLOYER

As a rule an employer adopts a plant medical program containing functions beyond his legal obligation because he is convinced that such practices represent an improvement in the conduct of his business. Therefore a physician who is asked to supply these services should make it a point to comprehend the nature of the business with which he is to be associated and to understand how and why he can be of value to it. The essential purpose of any industry is the development of goods and services of such quality and price as to permit the widest possible distribution. Procedures calculated to accomplish this purpose are well defined by custom and long experience in many industries. Elsewhere they may be exceedingly complicated. Often extensive consumer research is necessary, as well as designing of an engineering nature. Markets must be developed, sustained and augmented by advertising and efficient distribution. Competition must be met, restrictive legislation conformed with, and provision made for taxation and finance. Facilities for the conduct of the business must be provided with proper equipment so arranged as to promote efficient production. Workmen must be employed and trained for specific jobs under competent supervision. Sound business management requires that trained manpower be conserved, kept in good physical condition and maintained steadily at gainful employment. It is through the successful accomplishment of this maintenance function that the physician in industry can make himself most helpful and not infrequently indispensable.

VALUE TO THE EMPLOYEE

The first objective of all industrial health activity is to promote the physical welfare of every worker. Certainly the interests of employer and employee are most nearly identical under an arrangement which tends to reduce all loss of working time because of sickness or injury. Individual workers stand to gain substantially in every instance in which the industrial medical service is competently and fairly administered. The advantage to the worker rests not solely on improved earning power through steadier employment but by proper placement in work fitted to his physical and temperamental makeup.

SCOPE OF INDUSTRIAL HEALTH

These values, which have been assigned by employer and employee alike, are responsible for the growth of interest in industrial health and for increasing demands on physicians to supply medical services to industry. This interest has been

productive of much good as well as of some misdirection and abuse. The medical profession has as a result developed a point of view which has the intent of defining the proper scope of industrial medical activity and of unqualifiedly condemning conditions which make it impossible to maintain adequate standards of medical performance.

In keeping with this broad opinion, the Council on Industrial Health believes that a properly administered industrial health program should:

1. Prevent disease or injury in industry by the establishment of proper control over industrial environment.
2. Promote restoration to health and earning capacity as promptly as possible after industrial injury or disease.
3. Conserve the health of workmen through physical supervision and education.

These are expressions concerning scope and not of specific functions. On the acceptance of these principles rests the justification for the development of industrial health as a special field of medical interest distinct from private practice and through which at the same time the aims of industrial and private practice are reconciled.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT. HOWARD A. CARTER, Secretary.

PLASMATIC THERAPY INSTRUMENT NOT ACCEPTABLE

Manufacturer: Physical Medicine Instrument Company, Architects Building, Indianapolis.

At times, in order to fulfil its assumed obligations to the medical profession and to the public, the Council may consider itself called on to investigate and prepare reports on devices which have not been submitted, if such reports, in the opinion of the Council, are important to public health and welfare. The advertising and promotional matter distributed by the Physical Medicine Instrument Company have been inspected, and this report is based on them.

In the advertising used to promote the so-called Plasmatic-Therapy Instrument, F. B. Knyvett is designated as "Creator and developer of Plasmatic-Therapy." As part of the promotional matter Mr. Knyvett distributes a reprint of an article entitled "Pasturizing the Blood (Pyretotherapy with Conductive Heat)" in which are reported cases in which the Plasmatic-Therapy Instrument was used. Elsewhere in the advertising Knyvett writes that every case reported in the article was personally treated by him under the direction of a physician.

The Plasmatic-Therapy Instrument is described in the article as "... an apparatus which will introduce heat into the circulating blood without altering the balance of temperature that is normally maintained by the healthy body, and that will accelerate and control the pulse rate to within five beats per minute. . . . The Plasmatic-Therapy apparatus directly heats the blood." It is stated that the apparatus should be very useful to the average clinician because it makes it possible for him "... to administer pyretotherapy, which appears to be in some respects just as effective as that attained by the production of artificial fever or hyperpyrexia" most conveniently in his office. In this manner, the article explains, it is possible to obtain the benefits of fever therapy with none of the attendant disadvantages such as hospitalizing the patient or employing specially trained technicians, and it is possible to do this with an instrument much less costly than the apparatus used in fever therapy. The treatment is said to involve practically no discomfort to the patient, and shortly after the treatment is completed it is possible for him "... to safely dress and go about his business." The technic for "plasmatic" therapy treatment is said to be as follows:

"In basic outline, the plasmatic therapy treatment consists of surrounding the patient with two special long, narrow, heating units, each of which extends from the axilla, under the sole of the foot, and up the inside of the leg and thigh to the groin, where the two are connected. He is then enveloped in a sheet,

a blanket or two, and a special rubber blanket. None of these coverings is wrapped so tightly as to constrict any part of the body enough to cause discomfort. The current, coming through an ingeniously constructed adjusting, timing, and regulating cabinet, is then turned on, and will be automatically turned off at the end of a predetermined period—from 30 to 60 minutes or more, as desired. Meantime the patient's pulse and temperature may be taken and recorded about every 10 minutes. Sweat should be wiped from the face as it collects, and water given through a drinking tube, as and if desired by the patient. This very simple attention which requires no special technical training, is all that is necessary unless definite discomfort should develop. . . ."

Ten cases are then reported in which this therapy was used. It is claimed that most of the patients had been previously treated by conventional or established methods which had failed to result in any improvement in the patient's condition. A series of plasmatic therapy treatments are said to have produced remarkable results in every case. In the case of a complete recovery from the effects of an attack of poliomyelitis, it is stated, "This case was investigated by representatives of the Press, and reported in the metropolitan newspapers."

The Council has often expressed the opinion that the administration of physical therapy and the use of physical therapy apparatus should be in the hands of trained individuals. To direct treatment intelligently it is imperative that the individual administering the treatment understand the technic so that he may avoid the dangers that may result from ignorance. Since the article advises that a person with no training is competent to administer the treatment, it leads the Council to believe that the exaggerated claims made for the instrument may not have been substantiated by careful clinical examination.

To promote the sale of the Plasmatic-Therapy Instrument a communication signed by F. B. Knyvett is addressed to physicians and contains this opening sentence: "Dear Doctor; Would you like to add \$600.00 a week to your income?" The "Earning Possibilities" of the Plasmatic-Therapy Instrument are then explained in detail and actual instances of physicians' earnings from the device are cited. For example, "A physician with offices in 57th Street, New York City, \$1800.00 in the first 3 weeks. . . . A town over 1,000,000; this physician never previously had even a lamp in his offices. From November 4th to November 21st, \$1265.00 in Cash Fees."

The question "Is A Special Technician Necessary For Such Work?" which is used as a heading in the letter is answered with these statements: "The answer is NO. Any office assistant can be taught in five minutes how to operate the instrument. Most physicians have found this an ideal way to make use of an otherwise idle office assistant—who previously only answered the phone during the Doctor's morning at the Hospital. Any such assistant can give from eight to ten treatments a day. After the first examination and authority for treatment, it is not necessary for the physician to be present at the Sessions."

In the section headed "What Are the Usual Fees For Treatment?" the physician is given this advice: "The most satisfactory manner in which to charge patients has been found to make a charge for a series of treatments—not so much for each individual treatment. The usual fee is \$75.00 for a series of eight treatments. A large number of your cases will be remitted in this number of treatments. In chronic conditions, such as multiple-sclerosis, post encephalitis, locomotor-ataxia, osteoarthritis, diabetes, endarteritis-obliterans, etc., you cannot hope to bring a patient to recovery in any such series. In such cases, the patients are charged \$50.00 for the second, and all other series, of 8 treatments each. Many physicians have received the surprise of their life, when a patient, suffering from a chronic condition, who is owing large sums for previous treatment, will go out and borrow the money for plasmatic-therapy treatment."

In another section of the promotional letter it is stated "We provide with the instrument a 100-page detailed instruction book covering the method of treatment, conditions suitable for treatment, attention to the patient during treatment and all other necessary data. In addition, we offer you proved suggestions on how to get new patients in an ethical and legitimate manner together with suggestions on what fees to charge, and how to collect them." This statement also is made: "We have had a

number of individuals from California to Maine, write us asking where they could obtain plasmatic-therapy treatment; the result of their reading an article on what had been accomplished by plasmatic-therapy, which they perused in a Journal in their own Physician's waiting room!"

The use of promotional material in which financial gain to the physician is stressed is highly objectionable. The implication is made in a promotional letter that the Plasmatic-Therapy Instrument has been submitted to and accepted by the American Medical Association. This implication is completely erroneous.

The Therm \mathbb{R} , manufactured by the Op-Al Electric and Manufacturing Company, Indianapolis, a device also promoted by Mr. Knyvett, was submitted to the Council on Physical Therapy in 1934. The unit was an elaborate device for the heating of various body orifices and consisted of a chromium-plated steel cabinet containing diversified controls and regulators, and a number of varieties and shapes of applicators. The device was investigated in the urology and physical therapy departments of a clinic acceptable to the Council. A report was sent to the firm, Sept. 16, 1935, stating that "Because of the unfavorable clinical report, and because of the failure of the firm to submit acceptable advertising matter, the Council on Physical Therapy voted not to include the Therm \mathbb{R} apparatus in its list of accepted apparatus." The report was not published in THE JOURNAL because, according to information received from the firm, the unit was no longer being manufactured.

A nine page advertising booklet entitled "The Blood is the Life" (a Biblical quotation), copyrighted by F. B. Knyvett, is said to explain the theory behind "Plasmatic-Therapy." Four pages of the booklet are used to inform the reader that blood is the vital fluid of life and that the plasma is an important part of the blood. On page 7 this statement is made: "If Pasteur was able to destroy all harmful bacteria in milk, wine, and other foods, by the action of controlled heat, it would certainly be within the bonds of possibility that we can do the same thing in the living blood!" Thus is Plasmatic-Therapy said to be a method of "... introducing heat DIRECTLY into the blood stream ... !" or of "Pasteurizing the Blood!"

It is the opinion of the Council that insufficient critical evidence has been presented to substantiate the claims made for the instrument by the firm, and that the manner in which the apparatus is advertised and promoted is detrimental to the interests of both the public and the medical profession. The Council voted not to include the Plasmatic-Therapy Instrument on its list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

LIVER AND STOMACH PREPARATIONS (See New and Nonofficial Remedies, 1940, p. 320)

POWDERS FOR ORAL ADMINISTRATION

(See New and Nonofficial Remedies, 1940, p. 323)

LIVER EXTRACT-ABBOTT.—A dried, powdered, nitrogenous, fat-free, water-soluble extract, prepared from fresh mammalian livers. The daily oral dose of approximately 25 Gm. (fifty capsules) has been found to produce the standard reticulocyte response defined as 1 U. S. P. unit (oral) when assayed in cases of pernicious anemia as required by the Council.

Actions and Uses.—Liver extract-Abbott is used in the treatment of pernicious anemia. See the general article Liver and Stomach Preparations, New and Nonofficial Remedies, 1940, p. 320.

Dosage.—Initial dose fifty capsules (approximately 25 Gm.) daily until examination shows a satisfactory blood cell count. The dosage is then kept at a level which will maintain remission.

Distributed by Abbott Laboratories, North Chicago, Ill. No U. S. patent or trademark.

Fresh edible liver is extracted with water at 170 F. for thirty minutes and filtered. The filtrate is concentrated in vacuo and then dried in vacuo. The dried material is powdered and filled into capsules. Each capsule contains the extract from 10 Gm. of fresh liver.

SOLUTION FOR PARENTERAL ADMINISTRATION

(See New and Nonofficial Remedies, 1940, p. 327)

LIVER EXTRACT (INJECTABLE) U. S. P.-ABBOTT, 5 UNITS PER CC.—A sterile aqueous solution of liver preserved with 0.5 per cent of phenol. The daily parenteral administration of 0.2 cc. has been found to produce the standard reticulocyte response defined as 1 U. S. P. unit (injectable) when assayed in cases of pernicious anemia as required by the Council.

Actions and Uses.—Injectable liver extract U. S. P.-Abbott is used for intramuscular injection in the treatment of pernicious anemia. See the general article Liver and Stomach Preparations, New and Nonofficial Remedies, 1940, p. 320.

Dosage.—Daily intramuscular injections of from 0.5 to 1 cc. may be given until the reticulocyte peak has been reached. The dosage is then kept at a level which will maintain remission.

Distributed by Abbott Laboratories, North Chicago, Ill. No U. S. patent or trademark.

Injectable Liver Extract, U. S. P.-Abbott (5 U. S. P. units per cc.), 10 cc. vial.

Injectable Liver Extract, U. S. P.-Abbott (5 U. S. P. units per cc.), 50 cc. vial.

Fresh edible liver is extracted with water at 170 F. for thirty minutes and filtered. The filtrate is concentrated in vacuo and extracted with 70 per cent alcohol; the alcoholic extracts concentrated in vacuo and precipitated with ammonium sulfate. The precipitate is further purified by alcoholic fractionation, the alcohol removed and the extract made up to volume so that each cubic centimeter contains the extract from 50 Gm. of fresh liver. Five tenths per cent phenol is used as a preservative.

SOLUTION FOR PARENTERAL ADMINISTRATION

(See New and Nonofficial Remedies, 1940, p. 327)

LIVER EXTRACT (INJECTABLE) U. S. P.-ABBOTT, 10 UNITS PER CC.—A sterile aqueous solution of liver preserved with 0.5 per cent of phenol. The daily parenteral administration of 0.1 cc. has been found to produce the standard reticulocyte response defined as 1 U. S. P. unit (injectable) when assayed in cases of pernicious anemia as required by the Council.

Actions and Uses.—Injectable liver extract U. S. P.-Abbott is used for intramuscular injection in the treatment of pernicious anemia. See the general article Liver and Stomach Preparations, New and Nonofficial Remedies, 1940, p. 320.

Dosage.—Daily intramuscular injections of from 0.25 to 0.5 cc. may be given until the reticulocyte peak has been reached. The dose is then kept at a level which will maintain remission.

Distributed by Abbott Laboratories, North Chicago, Ill. No U. S. patent or trademark.

Injectable Liver Extract, U. S. P.-Abbott (10 U. S. P. units per cc.), 5 cc. vial.

Injectable Liver Extract, U. S. P.-Abbott (10 U. S. P. units per cc.), 10 cc. vial.

Injectable Liver Extract, U. S. P.-Abbott (10 U. S. P. units per cc.), 30 cc. vial.

Fresh edible liver is extracted with water at 170 F. for thirty minutes and filtered. The filtrate is concentrated in vacuo and extracted with 70 per cent alcohol; the alcoholic extracts are concentrated in vacuo and precipitated with ammonium sulfate. The precipitate is further purified by alcoholic fractionation, the alcohol removed and the extract made up to volume so that each cubic centimeter contains the extract from 100 Gm. of fresh liver. Five tenths per cent phenol is used as a preservative.

SULFAPYRIDINE-SODIUM (See J. A. M. A. March 30, 1940, p. 1156).

Sulfapyridine Sodium Monohydrate-Calco.—A brand of sulfapyridine sodium-N. N. R.

Manufactured by Calco Chemical Division American Cyanamid Co., Bound Brook, N. J. U. S. patent applied for. No U. S. trademark.

SULFANILAMIDE (See New and Nonofficial Remedies, 1940, p. 489).

The following dosage form has been accepted:

Tablets Sulfanilamide, 5 grains.

Prepared by Flint, Eaton & Company, Decatur, Ill. No U. S. patent or trademark.

THIAMIN CHLORIDE (See New and Nonofficial Remedies, 1940, p. 528).

Thiamine Hydrochloride-Merrell.—A brand of thiamin chloride-N. N. R.

Manufactured by the William S. Merrell Company, Cincinnati.

Ampuls Solution Thiamine Hydrochloride 1.0 mg., 1 cc.

Ampuls Solution Thiamine Hydrochloride 6.0 mg., 1 cc.

Ampuls Solution Thiamine Hydrochloride 10.0 mg., 1 cc.

Thiamine Hydrochloride Tablets-Merrell, 1.0 mg.

Thiamine Hydrochloride Tablets-Merrell, 3.0 mg.

PHYSICIANS NEEDED FOR INDUCTION BOARDS

After registrants are accepted by local draft boards they will be sent for physical examination to medical induction boards. About one hundred such boards will be set up throughout the country, about half of them near army posts and stations. Each board will consist of three internists, one general surgeon, one orthopedic surgeon, two ophthalmologists, one otorhinolaryngologist, one neuropsychiatrist, one clinical pathologist and one dentist.

As explained by Colonel Love last week in *The Journal* (pages 1201-1202), the specialists to be assigned to such service will probably include civilian specialists as well as reserve officers, who will be on temporary duty. Civilian physicians will be on a per diem basis and will be used as long as their services are required. It has been proposed that they be paid at the base pay of major with allowances for travel and subsistence while on duty. Physicians preferred for this service are those who, on account either of age or of physical infirmities or because of reasons affecting their civil life, cannot go into military camp. It has been tentatively estimated that the time required for this service might approximate twenty to thirty days in the period between October 16 and February 1.

In order to aid the Army Medical Department in securing physicians for this service, the Committee on Medical Preparedness requests physicians who wish to volunteer to write at once to the Committee on Medical Preparedness, 535 North Dearborn Street, Chicago, marking the envelop "Induction Boards."

THE MEDICAL CONTROL OF MOBILIZATION

The medical problems presented by mobilization are already taxing the ingenuity of those responsible for the program now pending. The late Hans Zinsser,¹ basing his reasoning on experiences in the mobilization camps in 1917, pointed out that outbreaks of epidemics are almost inevitable when large numbers of men from all over the country are brought together in camps under circumstances which call for arduous physical and disciplinary training. Much control over the epidemic intestinal diseases such as typhoid and dysentery can

be exerted by suitable preventive measures, but the situation with regard to respiratory diseases is more difficult. In such conditions as measles and mumps neither prevention nor treatment can be much better controlled than formerly. The importance of these diseases is emphasized by a citation of the figures: among the enlisted men who were serving in the United States during the year 1918 there were 102,950 cases of mumps.

Zinsser was convinced that the unimpeded flare-up of infectious diseases among young military units is stimulated by two factors: the too rapid bringing together of large numbers of susceptible young men with large numbers of carriers of the various respiratory organisms and the quite natural but too energetic efforts to force military training and the physical hardening process at a pace too strenuous for the relatively soft recruit. The evidence backing these beliefs is impressive and the countervailing measures suggested deserve practical trial. Such trial involves in part a change to a scheme of "gradual mobilization," which can be carried out in any one of a number of different ways. The assembly of large troop units can be developed in successive stages, beginning with small units and gradually joining these into larger units so that early medical supervision can be more carefully carried out. Military training or conditioning can be so graded that the necessary "hardening" is achieved without mass reduction of resistance to infection. The program adopted, however, should take into consideration the epidemiologic experiments of Greenwood and his co-workers,² some of whose conclusions, although carefully restricted to mice by them, deserve attention for their implications with regard to mobilization. Among them may be mentioned especially the conclusion concerning the general character of the epidemic process as revealed in herds of mice living in close and continuous contact and subject to the continuous or intermittent migration of susceptible individuals; thus it was shown that ectromelia, a virus disease of mice, under these circumstances will never normally die out.

Military mobilization presents a challenge and an opportunity. Available epidemiologic information such as that discussed must be utilized in planning each step of the assembly and care of the new recruits. The behavior of epidemic diseases under the different circumstances which develop must be carefully recorded and analyzed. Only by immediate concentration on these two objectives will it be possible to profit fully from the unique epidemiologic opportunity furnished by mobilization.

METHODS USED FOR IMPROVING ATHLETIC PERFORMANCE

The term "doping" was originally used to describe methods designed to increase the functional efficiency of athletes by means of highly active drugs. Now it is employed to describe any method of improving athletic performance temporarily either during training or in connection with competitive events. Bøje¹ has classified such substances into four groups: food preparations, oxygen, artificial sunlight and pharmaceutical substances.

Most of the food preparations, especially dextrose or sugar, which provide calories in a readily acceptable or otherwise suitable form are unobjectionable medically, Bøje feels. The evidence for the use of lecithin is not convincing and there seems to be no reason why it should be recommended for improving athletic performance. Similarly there is no experimental basis on which to recommend the use of yeast, although it does not appear to be deleterious. Conclusive evidence on the role of liver preparations in muscular work and its efficacy for increasing physical energy is also lacking.

Phosphates which have been employed can often cause a purely subjective feeling of freshness and zest for exercise which may amount to a condition of euphoria. Bøje concludes that phosphates taken in quantities exceeding the amounts found in a normally varied diet can probably increase the output of the organism. Although there is considerable loss of salts in heavy physical effort, this is probably insufficient to warrant administration of salts except in prolonged contests. Alkalis, usually in the form of sodium carbonate, have also been employed. Before deciding to administer them, attention should be given to the fact that the change produced by exertion in the p_H of the blood and its carbon dioxide tension influences among other things the regulation of respiration. Further, the administration of alkalis by mouth constitutes such a violent interference with the whole p_H regulatory system that it is as likely to be detrimental to the maximum physical output as the reverse. For a small group, such as aviators and mountaineers, ammonium chloride can be considered as an agent capable of increasing functional capacity. Other than for occasional slight local irritation, there can be no medical objection to its use.

The use of pure oxygen as a "dope" has been discussed from time to time. It may be granted that if it is administered immediately before the start of a contest, especially in the case of underwater swimming, it may exert some favorable effect. Nevertheless Bøje feels that most athletes and sports leaders have a fanciful and confused idea about the meaning of "oxygen priming" and that it is highly questionable whether the inhalation of oxygen is of any advantage in ordinary sports events.

Much has been said recently about the value of ultraviolet rays in connection with athletic training. Certainly if administered in suitable doses ultraviolet radiation should not produce any dangers, although athletes who are not used to ultraviolet rays should refrain from exposure immediately before taking part in competitions.

Pharmaceutical substances have been used in athletics based on their influence on the nervous system either as stimulants or as soothing agents. The toxic action of alcohol so overshadows its other effects that its role as a source of energy is of little athletic importance. Ether has been included by some as a "doping" agent but its use does not appear to assume any real importance in connection with sports. "Smelling salts," usually consisting of a solution of ammonia and of ammonium carbonate combined with ethereal oils, is popular in the prize ring and can be pronounced harmless.

Cocaine is one of the oldest known forms of "dope," although the extent to which it is now used by athletes is unknown. Leaving aside the question of whether or not it affects metabolism favorably, its influence on the central nervous system, which constitutes the motive for its use as a stimulant, cannot be questioned. Cocaine is effective in removing the sensation of fatigue and can in this manner undoubtedly raise the level of performance in the course of prolonged effort. This mechanism, however, is dangerous; it may have acute intoxicating effects when used in large doses. Its repeated use engenders addiction. Cocaine should never be used in connection with athletics.

Caffeine and other purine derivatives, although widely used as stimulants in connection with physical and mental effort, do not appear to have any established effects in connection with brief physical effort. Definite conclusions cannot be derived from the few available experiments on extended exercise. Furthermore, it is difficult to gauge how far coffee, chocolate and cocoa given to athletes in normal therapeutic doses as a physical stimulant can endanger their health. It seems likely that any substance capable of stimulating the body to exertion beyond the normal limits of fatigue set by the body will prove injurious.

Amphetamine sulfate is much more capable than caffeine of eliminating the sensation of fatigue; the overwhelming evidence of its toxicity, together with the fact that it is not definitely established that performance is improved, indicates that this substance should not be used in connection with athletics. Moreover, the application of extra stimuli or a weakening of natural powers of resistance in organisms undergoing a severe strain must involve risks.

The group of drugs including valerian, bromides and barbituric acid derivatives can be included, but there seems to be no danger of abuse among athletes since every one of these substances has powerful fatigue-producing properties. Digitalis and glyceryl trinitrate

1. Bøje, Ove: Doping: A Study of the Means Employed to Raise the Level of Performance in Sport, Bull. Health Organ., League of Nations S: 439, 1939.

likewise can be readily eliminated both because of insufficient evidence of their "doping" properties and because of their toxic effects. Nikethamide and metrazol have been employed by athletes because of their stimulating influence on the circulation and the central nervous system, which produces a definite subjective feeling of freshness in the tired organism. There is, however, nothing to show that recovery is improved and there are deleterious effects, especially in the convulsive properties of both substances. The use of such products by athletes should be definitely avoided. Finally, although various endocrine products have been tried the evidence on this subject is so flimsy that their use should be avoided, since it may involve dangers the extent of which cannot be evaluated.

Medical advisers must naturally strictly forbid the use of any agent suspected in any manner of being deleterious or any substance which may cause the least direct danger of whipping up the organism to extreme exertion. Although there can be little objection to the use of nutrient agents, of vitamins and of oxygen, the medical adviser should also do everything he can to discourage the use of costly and ineffectual substances.

Current Comment

THE CONSERVATION OF MEDICAL RESOURCES

An uninterrupted supply of qualified doctors of medicine to meet the future demands of adequate national preparedness and the needs of the civilian population is vital to the future of our nation. The Committee on Medical Preparedness of the American Medical Association urged last July that preparation for the conscription of the man power of this country should include provision for the continuation of medical education of students in medical schools and of interns in approved institutions. The Selective Training and Service Act of 1940 does defer the conscription of students in schools but only until next July. Specific deferment is not provided for those who may be completing their medical training as interns or as residents. An amendment has now been proposed to the Selective Training and Service Act of 1940 by Senator Murray of Montana in the form of a bill, S. 4396, providing that "medical and dental students at recognized medical and dental schools, and interns and resident physicians, surgeons and dentists at recognized hospitals" shall be exempt from training and service but not from registration. Any such student, intern or resident, the bill continues, who is a member of a reserve component of the land or naval forces of the United States shall not be ordered or called to active duty or into active service in any such forces without his consent, except in time of war. Finally it is proposed that any person selected for training and service under the act (1) who has been awarded a degree of doctor of medicine or doctor of dental surgery by a recognized medical or dental school, (2) who holds a valid license

to practice medicine or dentistry and is engaged in such practice at the time of his selection, and (3) whose physical and mental fitness for such service has been satisfactorily determined shall in lieu of induction for training in service be commissioned as an officer in the Medical Department Reserve, Officers' Reserve Corps, and ordered into active military service of the United States as provided in the joint resolution approved Aug. 27, 1940, by which the President was authorized to call into active service members of the National Guard and Reserve components of the Army. Senator Murray's bill was referred to the Senate Committee on Military Affairs. A companion bill, H. R. 10587, is pending in the House Committee on Military Affairs. Until and unless these measures become law interns, medical students and residents should provide for local selective service boards information and affidavits indicating their desire for exemption because of essential work for the public health.

THE SCIENTIFIC EXHIBIT

As the years have passed, the Scientific Exhibit of the American Medical Association, which began with a few demonstrations made by pathologists, has developed into a vast assemblage of the newest research in all the fields of medical science presented by those who are doing the work. The demonstration recently held in New York represented the very peak of what is accomplished for the graduate education of physicians by an exhibit of this kind. In the current issue of the *American Journal of Public Health* Dr. D. B. Armstrong and John Lentz publish a survey of health interests and present the following comment regarding the Scientific Exhibit in New York:

The Scientific Exhibit, an annual feature of the conventions of the American Medical Association, was viewed by thousands of physicians and representatives of related professions during the recent meeting in New York City. No one who witnessed the 1940 array of exhibits could fail to be impressed by the fact that it constituted a remarkable demonstration of the amount and variety of research and of professional education that are being undertaken under all kinds of medical auspices today. The exhibit particularly reflected the serious and exhaustive inquiries into the mysteries of medicine that are being made by private practitioners and by voluntary groups of medical men. It emphasized the great effort to enhance precision and utility as regards diagnosis and treatment in the many fields of specialization. The keen study given the exhibits by the thousands of professional visitors was another most encouraging sign.

Critics of medicine have classified it as a sordid trade or a moribund science—characterizations with which all would disagree who had the privilege of seeing the manifest growth, vitality and scientific integrity evidenced by the Scientific Exhibit at the 1940 and previous conventions of the American Medical Association. The threats of litigation and regimentation in medicine are unimportant and transient when measured against the long-time and far reaching significance of this demonstration of medicine's perpetual search for truth in its service to mankind.

On many occasions, physicians have said that a survey of this exhibit by those who are most vociferous in their attacks on modern organized medicine would serve to do much to put in their minds a wholesome respect for the dignity and the service of American medicine.

MEDICAL PREPAREDNESS

In this section of The Journal each week will appear official notices by the Committee on Medical Preparedness of the American Medical Association, announcements by the Surgeon Generals of the Army, Navy and Public Health Service, and other governmental agencies dealing with medical preparedness, and such other information and announcements as will be useful to the medical profession.

CAUSES FOR REJECTION FOR ENTRANCE INTO THE REGULAR ARMY DUE TO PHYSICAL DEFECTS

GEORGE E. LEONE, M.D.

Captain, Medical Corps, U. S. Army; Medical Inspector for
Recruiting, Second Corps Area

New York

In a preliminary statistical report on the causes for rejection due to physical defects of applicants for enlistment into the Regular Army of the United States some interesting observations were made. The report covered a three month period, June, July, August 1940, of applicants examined physically in the Southern New York District of the Second Corps Area, which includes New York City proper. These examinations were conducted by full time medical examiners under the direct supervision of Regular Army medical officers at 39 Whitehall Street, New York City. The applicants were for original enlistment into the Regular Army during an intensive recruiting campaign and the physical standards as set forth by the War Department, Army Regulations 40-105, were applicable. The age group included young men between the ages of 18 and 35, unmarried, citizens of the United States, having no record of conviction of a felony, and having the education or equivalent of the eighth grade. Many were high school and college graduates.

The total number of applicants covered by this report was 6,743, and of this total 2,195 were rejected for failure to meet the physical requirements. Thus more than 32.5 per cent, or nearly one third of all the applicants who presented themselves for physical examination, having had the other qualifications, were found physically unfit to become soldiers of the Regular Army.

What were the causes for these rejections? The major causes revealed by this report were failure to meet the requirements with regard to the following, in the order of their importance numerically:

1. Teeth.
2. Eyes.
3. Height and weight (stature).
4. Feet.
5. Ears.

Teeth.—Failure to meet the dental requirements stands out as the most important cause for rejection. Of the total number rejected during this period, that is, out of 2,195, there were 516 rejections due to teeth, more than 23 per cent of the total number rejected. It is difficult to convince young men that good sound teeth are necessary for healthy soldiers and more than one disappointed applicant who has been rejected because of poor teeth has exclaimed "What is the idea? Do we have to bite the enemy?" A minimum number of serviceable teeth have been set down as the require-

ments and it was amazing to find how many young men who have attended our public educational institutions failed to come up to these minimum requirements. It is well known that the condition of the teeth is a fairly reliable criterion on the general health and habits of young men. An indirect service was done for these young men who were rejected when the poor oral hygiene was called to their attention, and many expressed surprise and desire for corrective measures.

The requirements for teeth as set forth by Army Regulations are "a minimum of three serviceable natural masticating teeth above and three below opposing and three serviceable natural incisors above and three below opposing." Therefore the minimum requirements consist of a total of six masticating teeth and six incisor teeth. All these teeth must be so opposed as to serve the purpose of incision and mastication. Masticating teeth include molar and bicuspid teeth, incisors include incisor and cuspid teeth. Teeth which are involved with severe caries are not to be considered serviceable.

Eyes.—The next in importance as a major cause for rejection was the failure to meet the requirements in vision; 479 applicants, or 21 per cent of the total number rejected, were in this group. Most of these young men who could not see well enough to become soldiers did not wear glasses. Further classification of this particular group found most of them suffering from myopic astigmatism. Practically all of them had been driving motor vehicles and many could not be made to understand why they should be rejected, as they possessed operators' permits to drive.

Height and Weight (stature).—Fifteen per cent, or 308, were rejected because of the inability to meet the requirements for height and weight, the majority falling in the group that were underweight for their height. Experience has shown that great disproportion in the weight and height relation may mean lack of resistance and they usually are the first to break down physically when up against the rigors of military service. Many of those underweight showed signs of undernourishment and were potential candidates for tuberculosis.

Feet.—A total of 213, or little more than 10 per cent, were rejected because of poor feet. The results from functional tests for good feet were used as a criterion rather than anatomic conformation. Many feet that appeared flat anatomically showed good function when subjected to some strenuous tests. A considerable number of overlapping and hammer toes were found among those who were wearing ill fitting shoes.

Ears.—The fifth major cause for rejection was due to failure to meet the hearing and ear requirements. There were 202, or 10 per cent, in this group. The majority of those rejected in this group were found to be suffering from purulent otitis media in acute or chronic form in one or both ears associated with impaired hearing.

Other Causes.—The accompanying table shows other causes for rejection. No attempt has been made to find the reason for these figures.

The high number of rejections for teeth surprised us. When we compared figures with upstate New York, however, the same ratio held. The majority, perhaps 75 per cent, of the men rejected for dental defects had conditions that were remediable with proper dental treatment and improved oral hygiene. Many teeth, although present, had to be considered unserviceable because of extensive caries. Again, had many of the men rejected for eye defects been equipped with the proper correctable lenses they would have met the requirements.

The table may differ in some respects from the figures to be obtained when the Selective Service Law becomes operative. It must be remembered, however, that the applicants in the group covered by the present report were volunteers—young men who believed they were physically fit to fight for the defense of their country. It is obvious, for instance, that few young men

who have the intelligence to become soldiers would voluntarily present themselves for service with the colors if they had active venereal disease. It is only when all the men in a certain age group are required to report for service that a higher percentage of this type of disease is found.

The reason for this report is to present in a preliminary way the major causes for the rejection of our youth from entrance into the Regular Army, especially with regard to the teeth, eyes and ears. It also gives our medical examiners a clue as to what to look for particularly in the examination of applicants. It is also hoped that some preventive and remediable measures may be instituted for the better preservation of the health of the youth of our nation. As a national defense measure this is of vital importance for the future.

Room 811, 39 Whitehall Street.

EVACUATION HOSPITAL ORGANIZED

In cooperation with the defense program of our country, an evacuation hospital has been organized among the staff of the University Hospital and of the faculty of the Ohio State University College of Medicine, comprising twenty-eight medical and two dental officers, with Dr. John W. Means in charge of the unit.

APPOINTMENT IN NAVY MEDICAL CORPS

The Surgeon General of the Navy, Rear Admiral Ross T. McIntire (M. C.), announces that the Medical Corps of the Navy is being increased in strength proportionate with the expanding Navy and the Marine Corps. Examinations for appointments as commissioned officers in the Medical Department of the Navy will be held Jan. 6-9, 1941.

Appointments are being made in the Medical Corps, United States Naval Reserve, of male citizens of the United States, graduates of class A medical schools, who are under 50 years of age and who meet the physical and professional requirements.

The examination to be held in January will be for appointment as assistant surgeon in the medical corps of the regular Navy, effective about two months from date of examination, and for acting assistant surgeon (intern), effective July 1, 1941. Requests for authorization to appear for these examinations should be submitted to the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., in sufficient time to permit the authorization to reach the applicant prior to Dec. 30, 1940.

Applicants for appointments as assistant surgeon must be citizens of the United States between the ages of 21 and 31, must be graduates of class A medical schools and must have completed one year of intern training in a hospital accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association.

Applicants for appointment as acting assistant surgeon (intern) are not required to submit evidence of previous intern training and are appointed for a period of eighteen months, during which time they serve as interns in the larger naval hospitals which are approved for intern training. After completion of one year of service, acting assistant surgeons are eligible for examination for appointment as assistant surgeons. Acting assistant surgeons and assistant surgeons receive the pay and allowances of a lieutenant (junior grade).

Service for medical officers is active professionally and attractive in the shore duty, sea and foreign shore station assignments. In the normal rotation of assignments every practicable consideration is given the officer's preference for the type of duty he desires. The Naval Medical School at Washington, D. C., offers a course of postgraduate instruction and instruction in those branches of medicine which apply particularly to the naval service. Under normal conditions newly appointed medical officers are assigned to this course on entry into the service or during their first few years of naval service.

Naval medical officers are encouraged to develop a specialty after they have completed their first cruise at sea. Shortly before completion of his sea duty, the Navy doctor may request special training in the Medical Department specialty in which he is interested. Such requests are acted on by a special board in the Bureau of Medicine and Surgery and, if approved, the Navy doctor is sent to a hospital for training and experience in that specialty for one year. On completion of this training, he is assigned to postgraduate instruction at one of the medical centers in the United States for a period up to one year, after which, as far as is practicable, he is retained in that type of duty. Some of the specialties in which qualifications may be obtained are surgery, medicine, otolaryngology, x-ray, laboratory,

pathology, public health, psychiatry, deep sea diving, aviation medicine (flight surgery), gas warfare and tropical medicine. Several officers have been trained in research particularly applying to problems arising in submarine and aviation activities.

The service affords excellent opportunities for professional advancement. Medical officers receive the same pay and allowances as other officers of the Navy in corresponding ranks and the equivalent amount of service.

A circular of information for applicants for appointment as medical officers of the Navy, containing full information regarding physical requirements, professional examinations, rates of pay and promotion and retirement data may be obtained by addressing the Bureau of Medicine and Surgery.

Applications for appointment in the Medical Corps of the United States Naval Reserve should be addressed to the commandant of the naval district in which the applicant resides. The addresses of the naval commandants may be obtained from the Bureau of Medicine and Surgery.

INSTRUCTION IN SOCIAL HYGIENE FOR NEW YORK NATIONAL GUARD

Lectures on social hygiene are to be presented in each of the armories where the National Guard will be on duty before being transferred to active camp life, through the cooperation of Dr. Lucius A. Salisbury, division surgeon of the New York State National Guard, and Dr. Claude C. Pierce, regional director for the U. S. Public Health Service in the New York area. In New York City, the bureau of social hygiene of the department of health will furnish to the armed forces facilities prepared during the past few years, including moving pictures, exhibits, posters and literature. There are also plans to take advantage of the formation of a home guard to offer modern education in social hygiene. Interested persons are invited to ask for complete information on the facilities available through the bureau of social hygiene, department of health, 125 Worth Street, New York, or from the U. S. Public Health Service, Sub-Treasury Building, Pine and Wall streets, New York. There is no charge.

COMBATING PROSTITUTION IN WIS- CONSIN ARMY CAMP

With the information that immoral interests, which have been known to follow armies in camp, have become motorized with the development of the automobile trailer, the Wisconsin State Board of Health became active in controlling prostitution about the big scale army maneuvers in that state during August.

State and federal agencies, including army officials, cooperated under special rules to protect the state from any concentration of vice involving the menace of venereal diseases. Under emergency rules, no parking of trailers was permitted without special permit in the encampment area, which covered about 1,000 square miles.

Law enforcement officials of six counties touching on the military area cooperated with the officials during the month, and about thirty state-local enforcement officials were deputized during the period.

Rules adopted prohibited the opening of new tourist camps, dance halls, road houses, food stands or carnivals in the area, the picking up of hitch hikers, and the operating of taxicabs without special permit outside of municipal boundaries in the area.

The board ruled that civilians coming into the military zone, reasonably suspected of having a venereal disease could be inspected or examined by proper medical authorities and, if found to be infected, were to be hospitalized, quarantined or excluded from the area; also that prostitutes should not be permitted in the military zone.

INDIANA PUBLISHES MILITARY MEDICINE NUMBER

The Indiana State Medical Association has devoted its journal for September to military medicine. On the cover appears a picture of Fort Benjamin Harrison with troops in the foreground and a photograph of a patient being removed from an ambulance. Included among the subjects covered in the original articles are "Rational Contribution to National Defense by the Medical Profession" by Elmer F. Straub, Indianapolis; "Early Treatment of Gunshot Wounds and Fractures," Dr. Hiram W. Orr, Lincoln, Neb.; "The Medical Service of the United States Army," Lieut. Col. Paul R. Hawley, Carlisle, Pa.; "The Problem of the Psychopath in Recruit Training of the U. S. Navy," Dr. Emory L. Dravo, Great Lakes; "The Medical Officer from Civil Life," Dr. Larue D. Carter, Indianapolis; "Gas," Elliott H. Parks, Indianapolis; "Aviation Medicine," Dr. Albert M. Mitchell, Terre Haute; "Medical Defense," Dr. Herman M. Baker, Evansville, and "Registration Required," Robinson Hitchcock, Indianapolis. Special articles include one on "Medical Preparedness."

PROGRAM OF THE WISCONSIN STAFF MEETING

The program of the staff meeting of the Wisconsin General Hospital, Madison, October 1, was given over to military preparedness. The following subjects were discussed by members of the medical corps of the Wisconsin National Guard: Col. William F. Lorenz, "The Physician and Selective Service"; Lieut. Col. William J. Bleckwenn, "Organization of the Medical Department of the Army," and Capt. Marc J. Musser, "Functions of the Medical Department of the Army." Captains Frederick J. Pohle, Anthony R. Curreri and Clayton P. Wageman of the medical reserve corps discussed the "Medical Problems encountered in Recent Second Army Maneuvers."

RESERVE OFFICERS IN PHILA- DELPHIA

The official bulletin of the Philadelphia County Medical Society reports that there are about 600 physicians and dentists in the Philadelphia area who are members of the Medical Reserves. There are about seventy-one physicians in the Naval Reserve.

The statement pointed out that many units of the National Guard are not filled up to their required strength and that, as the personnel must be increased at once, more medical officers will be required.

ORGANIZATION SECTION

MEDICAL LEGISLATION

DISTRICT OF COLUMBIA

Changes in Status.—H. R. 8665 has been reported to the House, providing for the issuance of a license to practice chiropractic in the District of Columbia to Lou Davis. H. R. 9284 has passed the Senate, providing for the issuance of a license to practice the healing art in the District of Columbia to Dr. A. L. Ridings.

MEDICAL BILLS IN CONGRESS

Changes in Status.—The conference committee on H. R. 960, extending the classified civil service of the United States, has reached an agreement and has submitted to the House and Senate a report in which it is recommended that the Hatch amendment, paving the way for the appointment of graduates of unapproved medical schools to civil positions in government service, be eliminated. H. R. 8613 has been reported to the Senate, proposing that any person who served as a member of the Army Nurse Corps or of the Navy Nurse Corps during the World War and continuously thereafter until May 13, 1926, and who was, prior to June 20, 1930, separated from said corps by reason of physical disability incurred in line of duty, shall, on her application therefor, be entitled to be placed on the retired list of the Nurse Corps of which she was a member. H. R. 10278 has been reported to the House, proposing that in time of war or during an emergency declared by the President or by Congress the Secretary of War may, in his discretion, dispense with any part of the examination for promotion in the Regular Army of officers of the Medical, Dental and Veterinary Corps, except those relating to physical examination.

Bills Introduced.—S. 4396, introduced by Senator Murray, Montana, and H. R. 10587, introduced, by request, by Representative McCormack, Massachusetts, propose to amend the Selective Training and Service Act of 1940 so as to provide that medical and dental students at recognized medical and dental schools, and interns and resident physicians, surgeons and dentists at recognized hospitals, shall be exempt from training and service under the act, but not from registration, and that any such medical or dental student, intern or resident who is a member of a reserve component of the land or naval forces of the United States shall not be ordered or called to active

duty or into active service in any such forces without his consent, except in time of war. The bills further provide that any man selected for training and service under the Selective Training and Service Act (1) who has been awarded a degree of doctor of medicine or doctor of dental surgery by a recognized medical or dental school, (2) who holds a valid license to practice medicine, surgery or dentistry in any state, territory or possession of the United States or the District of Columbia and is engaged in such practice at the time of his selection, and (3) whose physical and mental fitness for such training and service has been satisfactorily determined shall, in lieu of induction into the land or naval forces of the United States for such training and service, be commissioned as an officer in the Medical Department Reserve, Officers' Reserve Corps, and ordered into the active military service of the United States as provided in the joint resolution approved Aug. 27, 1940, by which the President was authorized to call into active service the National Guard and Reserve components of the Army. H. R. 10606, introduced by Representative Schwert, New York, proposes to enact a "National Preparedness Act of 1940 for Health Education, Physical Education and Recreation in Schools and School Camps." The provisions of the bill, if enacted, will be administered by the United States Commissioner of Education, who is to be authorized to apportion federal grants-in-aid to be made available to the states that develop programs embodying the requirements set forth in the bill, subject to the approval of the Commissioner of Education. A school program, the bill provides, shall include among other things a continuous school health service, not including medical and dental treatment, to determine at least annually the health status of each pupil, to aid in the protection of pupils against communicable diseases, to provide special adjustment and guidance for pupils in need of such services; health supervision to insure safe and sanitary school conditions and processes for healthful living; instruction for all pupils in health and safety, including among other related and essential topics, instruction in nutrition, dental hygiene, first aid, effects of narcotic drugs and alcohol, physical and mental hygiene, and the hygiene of home and family life and such services as will bring all pupils having correctible and remediable defects under the care and treatment of licensed practitioners "or the proper agencies."

WOMAN'S AUXILIARY

Pennsylvania

The auxiliary to the Lackawanna County Medical Society had its annual bridge-luncheon, July 1, at the Scranton Country Club. About 130 members and friends attended, including representatives of the auxiliary to the Lackawanna County dental and pharmaceutical societies. The auxiliary voted a contribution to the American Red Cross for war relief work.—About 100 members and guests of the auxiliary to the Lehigh County Medical Society were entertained at a garden party at the home of Dr. and Mrs. J. Edwin Minner of Egypt, July 9. The proceeds were devoted to the charity fund.

Utah

At the annual meeting of the auxiliary to the Utah State Medical Association, Ogden, August 29 to 31, the attendance was excellent. Presiding at all sessions was Mrs. J. J. Weight of Provo, the president. Dr. G. M. Fister, president of the Utah State Medical Association, gave an address of welcome, followed by an address by Dr. Henry Nelson of Ogden. The guest speaker for the Thursday luncheon was Mrs. V. E. Holcombe, president of the national auxiliary, who spoke in

behalf of the *Bulletin*, the official organ of the auxiliary. The report of the annual national meeting was given by Mrs. Claude Shields. "The First Woman Physician of Utah" by Mrs. John Z. Broun and an address by Dr. Alton Oschner of New Orleans were given at the afternoon session. Later the guests were taken up to Ogden Canyon to the summer home of Mrs. Ezra Rich. A bridge-garden party was held at the home of Mrs. Leslie A. Smith. Friday morning, Dr. James C. Carr, professor of medicine at Northwestern University Medical School, Chicago, gave an interesting account of the life of Dr. Rudolph Virchow, father of modern pathology. At a luncheon, Utah County gave a clever skit "Fadesius in Foodesius," an original comedy on diets. Friday afternoon, Mrs. L. J. Paul of Salt Lake City presented a symposium on public relations, introducing Drs. John Sharp, J. R. Morrell and Ivan Thompson as guest speakers. Mrs. Leslie Merrill spoke on "Health Programs for High Schools." The national president's subject for the day was "Being a Doctor's Wife Is Both an Art and a Career." In the evening, the ladies joined the doctors at a pageant, "Fifty Years of Medicine in Utah County." On Saturday morning the "Do's and Don'ts of Vacationing" was presented by women from Salt Lake County.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Changes in Health Officers.—The newspapers report the following recent changes in health officers:

Dr. Robert Webster Crowell, Mullins, S. C., appointed in Chilton County, succeeding Dr. Samuel D. Sturkie, Clanton, who resigned to join the Virginia State Department of Health with headquarters in Charlottesville.

Dr. Arthur M. Shelamer, Athens, in temporary charge of the Limestone County health unit, succeeding Dr. Frank M. Hall, Athens, who resigned for a year's study at Johns Hopkins School of Hygiene and Public Health.

Dr. Julian W. Davis, O'Donnell, Texas, in charge of Henry County, succeeding Dr. George E. Maddison, who resigned to offer his services to the Canadian army.

Dr. Thomas T. Box, health officer of Washington County with headquarters at Chatham, in charge of Choctaw County with offices in Butler, succeeding Dr. David B. Snelling who went to Greene County.

Dr. William A. Blake, formerly of Blountville, Tenn., succeeded Dr. Box in Washington County.

Dr. Isee L. Connell, Birmingham, appointed in Cleburne County, succeeding Dr. Frank R. Wood, Heflin, whose term expired.

Dr. Eldridge T. Norman, health officer of Marengo County, appointed in charge of Hale County, with headquarters in Greensboro, succeeding Dr. Benjamin M. Drake, who recently resigned.

Dr. Marion L. Shaddix, Phenix City, health officer in Russell County, has been transferred to Clay County in a similar capacity.

ARKANSAS

Ninth Course of Graduate Instruction.—The committee on postgraduate instruction, Arkansas Medical Society, is offering its ninth course of graduate instruction, October 16-17, in cooperation with the University of Arkansas School of Medicine, Little Rock. Guest speakers will be Drs. John M. T. Finney Jr., Baltimore, and Hubert M. Parker, Kansas City, Mo. Dr. Finney will discuss "Appendicitis" and "Diverticula of the Small Intestine" and Dr. Parker, "Calcium Therapy, Indications and Contraindications" and "Management of Symptoms in Patients Who Have Had Several Laparotomies." Other speakers will include:

Dr. Grady W. Reagan, Little Rock, Newer Methods in the Diagnosis and Treatment of Pylonephritis.

Dr. Clyde D. Rodgers, Little Rock, Sterility.

Dr. Barton A. Rhinehart, Little Rock, The Essentials of Normal Nutrition.

Dr. Charles C. Reed Jr., Little Rock, Intravenous Anesthesia with Pentothal Sodium.

Dr. Byron A. Bennett, Little Rock, The Therapeutic Indications for the Use of Hormonal Preparations in Gynecology.

Dr. John N. Compton, Little Rock, The Good and the Bad About Sulfanilamide and Related Drugs.

Refresher courses will be offered concurrently with the postgraduate course. They are intended to be a comprehensive review emphasizing fundamental anatomic, physiologic, pathologic and clinical aspects of the subjects presented. They will be informal, making use of patients and clinical case reports.

CALIFORNIA

Physicians' Bowling Team.—A movement is under way to form a physicians' bowling team, consisting in the beginning of teams made up by members of the Los Angeles Medical Association. The object is, however, to develop a statewide league and a national organization patterned after the American Medical Golfing Association, with annual tournaments in the city in which the American Medical Association has its annual session. Information may be obtained from Dr. Lewis W. Bremerman, 1709 West Eighth Street, Los Angeles.

Society News.—The Los Angeles Surgical Society was addressed, October 11, by Drs. Harold L. Thompson on "Traumatic Lesions of the Bowel"; E. Eric Larson, "Gastric Resection," and Vernon P. Thompson, "The Mechanical Problems of Femoral Neck Fractures." All are from Los Angeles.

—Dr. George P. Landegger, Los Angeles, will discuss "History of Art" before the Los Angeles Physicians' Art Society, October 15, and Mr. Leslie G. Walker, "Painting with Light." —The San Francisco County Medical Society devoted its meeting, October 8, to a discussion on "Can We Get Adequate Nursing Care?" The speakers were Dr. Anthony J. J. Rourke and Marjorie Hart, R.N.; Sally Heitman, R.N., and Helen Reynolds, R.N.

COLORADO

State Medical Election.—Dr. Guy C. Cary, Grand Junction, was chosen president-elect of the Colorado State Medical Society at its annual meeting, September 14, and Dr. William H. Halley, Denver, was inducted into the presidency. Dr. John S. Bouslog, Denver, is the constitutional secretary. The next annual session will be held in Estes Park, the date to be decided later.

DELAWARE

Society News.—The New Castle County Medical Society was addressed in Wilmington, September 17, by Louis Gershenfeld, Pharm.M., Philadelphia, on "Serums, Vaccines and Related Products," and Dr. Joseph R. Beck, Dover, "Statistics on Diphtheria Immunization in Delaware."

State Medical Election.—Dr. Emil R. Mayerberg, Wilmington, was elected president of the Medical Society of Delaware at its annual meeting in September, to succeed Dr. Bruce Barnes, Seaford. He will take office in January. Dr. Charles L. Munson, Wilmington, is the secretary. The next annual session will be held in Wilmington, the date to be decided later.

DISTRICT OF COLUMBIA

Personal.—Col. Norman L. McDiarmid, medical corps, U. S. Army, has been appointed superintendent of Columbia Hospital for Women, Washington, to succeed the late Col. Percy M. Ashburn, who died August 20. Colonel McDiarmid has been stationed in the headquarters of the fourth corps area, Atlanta.

Society News.—Dr. Max M. Strumia, Bryn Mawr, Pa., addressed a meeting of medical and dental officers of the U. S. Navy in Washington, October 7, on "The Preparation and Utilization of Blood Plasma in the Naval Service." —The Medical Society of the District of Columbia was addressed in Washington, October 9, by Dr. Lauritz S. Ylvisaker, associate medical director, Prudential Insurance Company of America, and Mr. Pearce Shepherd, associate actuary of the Prudential, on "The Importance of Heart Disease." The society will be addressed, October 30, by Drs. Hugh H. Young, Baltimore, on "The Use of Radium in Tumors of the Bladder and Prostate" and Arthur C. Christie, Washington, "Diagnosis and Treatment of Cancer of the Pharynx."

GEORGIA

District Meeting.—The Fifth District Medical Society will meet in Atlanta, October 17. The speakers will be Drs. Robert B. Greenblatt, Augusta, on "The Vaginal Smear as a Guide to Estrogenic Therapy"; Robert C. Pendergrass, Americus, "Unusual Lesions of Gastrointestinal Tract" and Richard Torpin, Augusta, "Roentgen Pelvimetry." Dr. Job C. Patterson, Cuthbert, president of the state medical association, will also speak.

IDAHO

Director of Health Resigns.—Dr. Howard L. McMartin, Boise, has resigned as director of public health of Idaho and has accepted a position as director of health of Maricopa County, Ariz.

State Medical Election.—Dr. Paul M. Ellis, Wallace, was chosen president-elect of the Idaho State Medical Association at its annual session, September 13, and Dr. Abram M. Newton, Pocatello, was installed as president. Dr. Franklin B. Jeppesen, Boise, was elected secretary. The next annual meeting will be held in Sun Valley, June 18-21.

ILLINOIS

Hospital News.—The new \$600,000 Lake County tuberculosis sanatorium was dedicated in Waukegan, August 18; Dr. Morris Fishbein, Editor of THE JOURNAL, Chicago, was the principal speaker, using for his subject "Campaign Against the White Plague."

Society News.—Dr. Millard F. Arbuckle, St. Louis, discussed "Diagnosis and Treatment of Lung Abscess" before the Jefferson-Hamilton County Medical Society in Mount Vernon, September 25. —Dr. Joseph E. Schaefer, Chicago, addressed the Macoupin County Medical Society in Carlinville, September 24, on "Lesions of the Mouth." —Dr. Arthur J. Fletcher, Danville, discussed poliomyelitis before the Saline County Medical Society in Eldorado, September 27. —A symposium on diseases of the biliary tract was presented before the Vermilion County Medical Society in Danville, October 3, by Drs. Rollo K. Packard, Percy E. Hopkins and Charles H. Phifer, Chicago. Dr. Edwin S. Hamilton, Kankakee, discussed "Organization of the Medical Profession for National Defense."

Dr. Wendell W. Brown, Collinsville, addressed the Madison County Medical Society in Collinsville, October 4, on "Indications and Applications of X-Ray and Radium Therapy in Gynecology."—At a meeting of the Stephenson County Medical Society in Freeport, October 17, Dr. Charles J. Drucek, Chicago, will speak on "Cancer of the Rectum."—The Whiteside County Medical Society will be addressed in Sterling, November 7, by Dr. Clifford J. Barborka, Chicago, on "Management of Gallbladder Disease."—Dr. James E. Graham, Springfield, discussed "Varicose Veins" before the Adams County Medical Society in Springfield, September 9.

Chicago

New Hygiene Clinics.—Three free social hygiene clinics have been opened in Cook County through funds obtained under the National Venereal Disease Control Act. The clinics are in the Berwyn, Maywood and Robbins health centers. Additional clinics will be opened soon in Cicero, Harvey and Chicago Heights.

Alumni Reunion.—An informal reception and open house will be held, October 16, to honor three new deans of the Chicago colleges of the University of Illinois. They are Dr. Raymond B. Allen, executive dean of the Chicago colleges; Howard M. Marjerson, D.D.S., dean of the college of dentistry, and Earl R. Serles, Ph.D., dean of the college of pharmacy. An invitation is extended to all alumni of the University of Illinois.

INDIANA

Society News.—The Tippecanoe County Medical Society was addressed in Lafayette, September 10, by Dr. Harold S. Hulbert, Chicago, on "Behavior Problems, What Can We Do?"

—Dr. Edwin L. Libbert, Lawrenceburg, addressed the Dearborn-Ohio County Medical Society in Lawrenceburg, June 27, on "Medical Physiotherapy."—The Indianapolis Medical Society will devote its meeting, October 15, to a symposium on tuberculosis with Drs. Charles J. McIntyre, Chester A. Stayton and Frank L. Jennings as the speakers. The society will be addressed, October 22, by Drs. Willis D. Gatch on "Surgical Aphorisms"; J. Neill Garber, "Clinical and Pathologic Aspects of Volkmann's Contractures" and James S. Browning, "Tests of Cardiac Function."

MARYLAND

Semiannual Meeting of State Society.—The Medical and Chirurgical Faculty of the State of Maryland held its semiannual meeting in Annapolis, October 9. Dr. Robert S. G. Welch, Annapolis, vice president, Anne Arundel County Medical Society, gave the address of welcome. Drs. William F. Rienhoff Jr., Baltimore, and William D. Stroud, Philadelphia, discussed "The Jaundiced Patient" and "Cardiology," respectively. Dr. Edward P. Thomas, Frederick, president, Medical and Chirurgical Faculty, also spoke.

Personal.—Dr. Louis B. Flexner, associate in anatomy at Johns Hopkins University School of Medicine, Baltimore, has been appointed research associate in the department of embryology of the Carnegie Institution of Washington in Baltimore, according to *Science*. He will continue to investigate chemical interchanges in mammalian development, making use of artificially radioactive substances in cooperation with the department of terrestrial magnetism of the Carnegie Institution. Herbert A. Pohl, Ph.D., has been appointed research assistant in the department of embryology and Dr. Alfred A. Gellhorn a research fellow. Dr. Ines Lopez Columbo de Allende, during the past year visiting fellow of the Argentine Association for the Advancement of Science at the University of Rochester, has been appointed to a Rockefeller traveling fellowship and will spend the year 1940-1941 in the department of embryology of the Carnegie Institution.

MASSACHUSETTS

Personal.—Dr. Edwin B. Astwood, associate in obstetrics at the Johns Hopkins University School of Medicine, Baltimore, has been appointed assistant professor of pharmacotherapy at Harvard Medical School, Boston. He will also be a member of the staff of Peter Bent Brigham Hospital.

New Publication on Mental Hygiene.—The Massachusetts Society for Mental Hygiene announces that it has started the publication of a quarterly magazine "*The Mental Health Sentinel*," the first issue of which will appear this month. The editorial staff consists of Dr. Henry B. Elkind, Boston, editor; Miss Bernice M. Henderson, associate editor; Dr. Douglas A. Thom, Boston, president of the society; Dr. Clarence A. Bonner, Danvers, and Dr. Harry C. Solomon, Boston.

MICHIGAN

Prizes for Medical Papers.—The Foster Welfare Foundation of Grand Rapids, founded under the will of the late Clara J. Foster of Newaygo, announces the offering of prizes for medical papers on the following terms: Three \$100 cash prizes will be awarded, one each for the hospital staff of Blodgett Memorial Hospital, Butterworth Hospital and St. Mary's Hospital, respectively, all of Grand Rapids. The prize will be awarded to the author or authors of the best medical paper written by a member of the staff of the hospital, provided the staff of such hospital produces at least five medical papers, including the winning paper, which have been accepted for publication by either a national or a state medical journal during the year commencing May 1, 1940, and ending May 1, 1941. Each paper submitted may be written by one or more persons and, in the event that it is written by more than one, the award will be divided proportionately among the authors. Besides the three \$100 prizes mentioned, there will be an additional grand prize of \$100 to be awarded to the writer or writers of the best medical paper produced during said year, and accepted for publication, by members of the staffs of the three hospitals. This prize may be won even though the author's hospital staff has not produced five such medical papers during the year or may be won by the same author or authors and with respect to the same paper which is awarded one of the hospital staff prizes if such hospital staff qualifies by producing five papers. Typewritten copies of each of the papers to be submitted for prizes must be in the hands of a medical committee not later than May 1, 1941, including the papers, if any, not submitted for prizes but which are necessary in order to qualify a particular hospital staff as having written five medical papers accepted for publication during the year. The local medical committee will comprise three doctors, one from each hospital staff, which shall be appointed by the president of the Kent County Medical Society, subject to the approval of the board of trustees of the Foster Welfare Foundation. The duty of this committee will be to administer the work of collecting the papers and arranging the details of awarding the prizes. The committee, however, will not act as judges, and its members will be eligible to compete for the prizes. The judges to pass on the papers will be appointed by the trustees of the Foster Welfare Foundation. The judges will be doctors not residing in Grand Rapids and preferably those on university staffs. A dinner will be held in June 1941, at which time the prizes will be awarded, together with a suitable medal or certificate to be given to each prize winner.

MINNESOTA

Clinical Program of Alumni Association.—The Minnesota Medical Alumni Association will conduct a one day clinical program, October 25, the day preceding the university homecoming celebration. Beginning at 9 o'clock in the morning there will be presented in the Eustis Amphitheatre of the University Hospitals a series of half hour demonstrations and lectures by members of the faculty and by members of the class of 1920, which is holding its twenty year celebration on the same day. The speakers will include Drs. Henry E. Michelson, Thomas J. Kinsella, Adalbert L. Dippel, Leo G. Rigler, George E. Fahr, Minneapolis; Siegfried F. Herrmann, Tacoma, Wash., and Ellexious T. Bell, Minneapolis. At the conclusion of the clinical program, the annual meeting of the association will be held under the leadership of Dr. Harold G. Benjamin, Minneapolis, president. The program will conclude with a luncheon.

MISSOURI

Personal.—Dr. Katherine Bain, St. Louis, has been appointed director of the division of research in child development in the U. S. Children's Bureau, it is reported. She will supervise research projects which the bureau has under way in various medical schools, dealing particularly with rickets and the newborn. Her headquarters will be in Washington, D. C. Dr. Bain graduated at Washington University School of Medicine, St. Louis, in 1925.

NEW JERSEY

Autumn Tuberculosis Meeting.—The New Jersey Tuberculosis League will hold its annual fall meeting at Plainfield, October 25, with the following speakers: Emil Frankel, Trenton, "The Sanatorium" in the New Jersey Tuberculosis Program"; Dr. Allen W. Freeman, Baltimore, "What Principles Should Guide the Programs of Tuberculosis Associations in the Light of the Epidemiology of Tuberculosis?" and Dr. Charles S. Prest, Brooklyn, "Mass Testing of the Adult Population."

NEW YORK

Society News.—Dr. William Thalheimer, New York, addressed the Medical Society of the County of Westchester, White Plains, September 17, on "The Use of Human Serum in Combating Infectious Diseases and in Treating Shock."—Dr. Arthur J. Wallingford, Albany, addressed the Dutchess County Medical Society, September 11, on gynecologic problems.—Dr. James P. Leake of the U. S. Public Health Service, Washington, D. C., addressed the Medical Society of the County of Nassau, Garden City, September 24, on "Communicable Disease Control."—The New York State Association of Public Health Laboratories will hold its mid-year meeting at the division of laboratories and research, State Department of Health, Albany, November 1.—Dr. Samuel A. Levine, Boston, addressed the Rochester Academy of Medicine, October 1, on errors in cardiac diagnosis.

New York City

Dr. Rappleye Named Commissioner of Hospitals.—Dr. Willard C. Rappleye, dean of the College of Physicians and Surgeons of Columbia University, has been appointed commissioner of hospitals, succeeding Dr. Sigismund S. Goldwater. Dr. Rappleye has been granted a fifteen months leave of absence from his university position. He was to begin his new work October 2. Born in Marinette, Wis., in 1892, Dr. Rappleye graduated at Harvard Medical School, Boston, in 1918. He was chief of clinical laboratories and instructor in biochemistry at the University of California, 1919-1920, and director of hospitals there in 1921. He was superintendent of the New Haven Hospital from 1922 to 1926 and professor of hospital administration at Yale University, 1922-1925; director of study, Commission on Medical Education, 1925-1932. He has been dean at Columbia since 1931 and professor of medical economics since 1932; acting dean of the School of Dental and Oral Surgery at Columbia, 1933-1934, and dean since 1934. Since 1933 Dr. Rappleye has been director of the New York Post-Graduate Medical School and Hospital. Dr. Goldwater recently resigned as commissioner of hospitals to devote full time as head of the Associated Hospital Service.

OHIO

Hospital News.—The Cleveland City Hospital is offering its third lecture course for practicing physicians during October. Lectures are held Mondays, Wednesdays and Fridays, each followed by a question period. Among the subjects to be covered are patch tests in contact dermatitis, how to give insulin, paranasal sinusitis, nonallergic asthma, various phases of heart disease, chemotherapeutic drugs, anemias and use of testosterone propionate.

Society News.—Dr. Roy R. Grinker, Chicago, will address the Academy of Medicine of Cincinnati, October 15, on "The Interrelation of Neurology, Psychiatry and Psycho-Analysis." Dr. Edwin P. Alyea, Durham, N. C., will be the speaker, October 22, on "Chemotherapy in Nonspecific Urinary Tract Infections."—Dr. Warren H. Cole, Chicago, addressed the Montgomery County Medical Society, Dayton, October 4, on "Diseases of the Gallbladder."

Veteran Physicians Honored.—Six Lorain County physicians who have practiced more than forty-five years were honored at a dinner given by the Lorain County Medical Society, Lorain, September 10. They were Drs. Olney B. Monosmith and William E. Wheatley, Lorain; George E. French and Austin S. McKittrick, Elyria; George C. Jameson, Oberlin, and Frank B. Gregg, Wellington.—Dr. William B. Litten, West Bedford, was the guest of honor at a reception recently celebrating his sixtieth year of practice.

OKLAHOMA

Personal.—Dr. James T. Bell, Woodward, has been appointed director of the department of maternal and child health in the state department of health to succeed Dr. Paul J. Collopy, Oklahoma City, who resigned to join the staff of the Children's Hospital, Seattle, Wash.—Dr. Louis N. Dakil, Mayetta, Kan., has been appointed physician of the Quz paw Indian Agency with headquarters in Miami, succeeding Dr. Joseph H. Coogan, transferred to an agency in Nevada.

Another Medical Supplement.—The *Daily Oklahoman*, Oklahoma City, published a medical supplement, September 22, in cooperation with the Oklahoma County Medical Association. The supplement was published in tabloid form and consisted of twenty pages, the front page being devoted to an original drawing in color. In an editor's note it was stated that "For ethical reasons it has been impossible to use the names of

various doctors on many stories appearing in this section. On others, more general in scope, use of names has been permitted. In every instance the material has been prepared by competent authorities in the various fields." A similar supplement was published in September 1939.

PENNSYLVANIA

Society News.—Speakers at a meeting of the Clearfield County Medical Society, Philipsburg, September 26, were Drs. George P. Müller, Philadelphia, on "Treatment of Surgical Complications of Peptic Ulcer"; Edward L. Bortz, Philadelphia, "Modern Treatment of the Diabetic," and William Raymond McKenzie, Baltimore, "Cancer of the Larynx."—Herbert Koepp-Baker, associate professor of speech, Pennsylvania State College, State College, addressed the Lycoming County Medical Society, Williamsport, September 13, on "Speech Disorders."

Philadelphia

Sale of Raw Milk Banned.—Sale of unpasteurized milk for human consumption was banned in Philadelphia, October 1, under a new regulation of the board of health. Certified milk is excepted. About 8,000 quarts of raw milk is sold daily in Philadelphia out of a total of 800,000 quarts consumed. It is produced on twenty-one model farms under supervision of a raw milk commission set up four years ago, according to a newspaper account. Under the new plan they will be compelled to pasteurize the milk if it is sold in Philadelphia.

Society News.—A doctors' and dentists' night was observed by the Philadelphia County Medical Society, October 9, with Drs. Lester W. Burket and Robert H. Ivy as the speakers on "The Equal Importance of Mouth Lesions to Physicians and Dentists" and "Diagnosis of Lesions of the Mouth and Jaw" respectively. Both speakers are also dentists. The meeting was arranged in collaboration with the Philadelphia County Dental Society.—Speakers at a meeting of the Obstetrical Society of Philadelphia, October 3, were Drs. Clarence C. Briscoe and Robert A. Wilson, Brooklyn, on "Emergency Control of Postpartum Hemorrhage: Experience with the Supplementary Technic" and William G. Leaman Jr., "Some Cardiological Factors of Importance in Obstetric Practice."—Dr. John B. Flick addressed the Philadelphia Academy of Surgery, October 7, on "Lobectomy for Chronic Pulmonary Suppuration."

SOUTH CAROLINA

District Meeting.—A semiannual meeting of the Second District Medical Society was held in Columbia recently with the following speakers: Drs. Paul H. Ringer, Asheville, N. C., on "General Management of Tuberculosis"; David S. Asbill, Columbia, "Concretions in the Nose and Throat," and Francis E. Zemp, Columbia, "Helpful Points in Determining Heart Disease."

Society News.—The Fairfield County Medical Society, which had been inactive for several years, was reorganized at a recent meeting in Winnsboro. Officers elected included Drs. John C. Buchanan Jr., president; Samuel Lindsay, vice president, and Charles S. McCants, secretary.—Lieut. Col. Clyde C. Johnston, surgeon of the Eighth Division, U. S. Army, Fort Worth, Texas, addressed the Columbia Medical Society, Columbia, September 9, on "Military Medicine."

Personal.—Dr. Joseph H. King, Summerton, has been appointed health officer of Chester County to succeed Dr. Yeadon M. Hyer, recently transferred to Hampton and Alledale counties.—Dr. Lloyd W. Luttrell, Spartanburg, has been named health officer of Pickens County.—A portrait of Dr. Jane Bruce Guignard, Columbia, was presented to the Columbia Hospital, September 24, by her patients. Dr. Guignard was graduated from the Woman's Medical College of Pennsylvania in 1904 and has practiced in Columbia since 1905.

WASHINGTON

New Health Officers.—Dr. Lawrence E. Foster, formerly of Monticello, Ill., has been appointed head of a new health unit in Jefferson County, with headquarters in Port Townsend.—Dr. Ralph M. DeBit, Kennewick, has been appointed health officer and county physician of Benton County, succeeding the late Dr. LeGrand Spaulding. Dr. Russel L. Baker, White Salmon, has been appointed health officer for Klickitat County.

Society News.—Speakers before the King County Medical Society, Seattle, September 16, were Drs. Kenneth K. Sherwood, on "Medical Aspects of Postoperative Complications"; John E. Nelson, "Appraisal of the Tuberculin Tests," and Pius A. Rohrer, "Renal Tuberculosis—A Follow-Up Study."

All are from Seattle.—A round table discussion of cancer was presented at a meeting of the Spokane County Medical Society, Spokane, September 12, by Drs. Horace J. Whitacre, Tacoma, as interrogator; James M. Nelson, Spokane, discussing surgery; Bernard D. Harrington, Tacoma, radiology; George A. C. Snyder, Spokane, pathology, and Donald G. Corbett, Spokane, urology.

WISCONSIN

Personal.—Dr. Jefferson F. Klepfer, acting superintendent of the Central State Hospital for the Insane, Waupun, since the death of Dr. William A. Deerhake, April 10, has been appointed superintendent.

Society News.—Drs. George B. Noyes, Centuria, and Anton N. Nelson, Clear Lake, addressed the Polk County Medical Society, Amery, August 15, on "Inguinal Hernia in Small Infants" and "Speech Defects" respectively.—Drs. Robert S. Baldwin and Stephen Epstein, Marshfield, addressed the Trempealeau-Jackson-Buffalo Counties Medical Society in Blair, August 22, on "Management of Diabetes" and "Common Skin Diseases" respectively.—Drs. Henry A. Romberg and Reuben H. D. Bitter, Oshkosh, addressed the Winnebago County Medical Society, Oshkosh, September 5, on military medical service.

ALASKA

Dr. Worley Transferred to Minneapolis.—Dr. James F. Worley, senior surgeon, U. S. Public Health Service, medical director of the Alaska division of the Indian Medical Service, Juneau, has been transferred to Minneapolis as medical director of district number 1, comprising the states of Michigan, Wisconsin, Minnesota, Iowa, Nebraska and North and South Dakota.

HAWAII

Society News.—Dr. Theodore L. Althausen, San Francisco, addressed the Hawaii County Medical Society, Hilo, August 6, on "Clinical Management of the Disturbance of Carbohydrate Metabolism in Hyperthyroidism." In July Dr. Ludwig A. Emge, San Francisco, gave a series of lectures on obstetrics under the auspices of the bureau of maternal and infant hygiene, and Dr. Isidor S. Ravdin, Philadelphia, lectured recently on "Gastric and Duodenal Ulcers," "Problems of the Biliary Tract" and "Preoperative and Postoperative Treatment." Dr. Ravdin also held a surgical clinic at the Hilo Memorial Hospital.

GENERAL

Aero Medical Association.—The twelfth annual meeting of the Aero Medical Association of the United States will be held in Memphis, Tenn., October 25-27, with headquarters at the Hotel Peabody. Among papers announced in the preliminary program are:

Dr. Walter M. Bartlett, Benton Harbor, Mich., The Use of Combined Electrocardiography, Electroretinography and Cardioscopy in the Early Recognition of Heart Disease as Especially Applied to the Selection of Pilots.

Capt. Otis A. Benson Jr., U. S. Army, Data of Experimental Work from the Metabolism Laboratory of the Mayo Clinic.

Dr. Edward J. Van Lier, Morgantown, W. Va., The Effect of Anoxia on the Digestive Processes.

Association of Medical Colleges.—The fifty-first annual meeting of the Association of American Medical Colleges will be held at the University of Michigan, Ann Arbor, October 28-30. The speakers will include:

Dr. Willard C. Rappleye, New York, The Internship.

Dr. James D. Bruce, Ann Arbor, The Expanding Phases of Postgraduate Medical Education.

Donald E. Cummings, B.S., Denver, Industrial Hygiene Instruction for Medical Students.

Dr. Burton D. Myers, Bloomington, Ind., Teaching of Anatomy.

Dr. Paul D. Lamson, Nashville, Tenn., Teaching of Pharmacology.

Dr. Linn J. Boyd, New York, Some Observations on the Teaching of Pharmacology.

George H. Smith, Ph.D., New Haven, Conn., Teaching of Bacteriology.

Dr. George E. Wakerlin, Chicago, A Plan for the Protection of Medical Research.

Society News.—Dr. Abraham R. Hollender, Miami Beach, Fla., was chosen president-elect of the American Congress of Physical Therapy at the annual meeting in Cleveland, September 2-6, and Dr. Nathan H. Polmer, New Orleans, was installed as president. The following were elected vice presidents: Drs. Fred B. Moor, Los Angeles; Kristian G. Hansson, New York; Miland E. Knapp, Minneapolis; Walter S. McClellan, Saratoga Springs, N. Y., and Herbert Worley Kendall, Dayton, Ohio. Dr. Richards Kovacs, New York, is the secretary. The annual awards of merit were presented to Drs. Hollender; George W. Crile, Cleveland; Disraeli W.

Kobak, Malcolm T. MacEachern and William F. Petersen, Chicago; Horatio B. Williams, New York, and Charles F. Kettering, Sc.D., Dayton, Ohio, general manager of the research laboratories of the General Motors Corporation and founder of the Kettering Department of Medical Research at the Miami Valley Hospital, Dayton.

American Dietetic Association.—At the annual meeting of the American Dietetic Association at the Hotel Pennsylvania, October 20-24, the program will include the following medical papers:

Dr. Eugene F. Du Bois, New York, Fewer and Better Diets.

Dr. Carroll E. Palmer, U. S. Public Health Service, Appraising Vitamin Status from the Standpoint of Normal Nutrition.

Dr. Norman H. Jolliffe, New York, Recent Advances in Clinical Applications of the B Vitamins.

Dr. Abraham H. Aaron, Buffalo, Diet in Diseases of the Digestive Tract.

Dr. Dana W. Atchley, New York, Water Metabolism.

Dr. John D. Stewart, Boston, Nutritional Care of Surgical Patients.

Dr. Herbert Pollack, New York, What the Dietitian Should Know About Clinical Laboratory Methods.

Dr. William Schmidt, New York, Nutritional Deficiencies of Adolescence.

Dr. William S. Langford, New York, Psychological Aspects of Feeding in Early Childhood.

Changes in Status of Licensure.—The New York State Board of Medical Examiners has recently reported the following action:

Dr. Irving Klinger, New York, license suspended, July 19, for one year.

Dr. Nicholas A. Tonis, New York, license suspended, July 19, for one year.

Dr. Emanuel L. Stammer, Jamaica, license suspended, July 19, for one year.

The State Medical Board of Ohio has reported the following action:

Dr. Reuben B. Jackson, Nashville, Tenn., Ohio license based on reciprocity with Tennessee revoked, July 2, following his conviction for violation of the federal narcotic laws.

Dr. Weah N. Sherrill, Cincinnati, license revoked, July 2, for conviction of a felony and violation of the federal narcotic laws.

The Wisconsin State Board of Medical Examiners reports the following action:

Dr. Elgie Kraut, Lancaster, license restored July 9.

Conference on Applied Nuclear Physics.—The American Institute of Physics in cooperation with the Massachusetts Institute of Technology will hold a Conference on Applied Nuclear Physics at the Institute in Cambridge, Mass., October 28 to November 2. The activities will be divided into separate sessions on applications to biology, chemistry, radiology, metallurgy, geology and general sessions relating to the production and use of radioactive and stable isotopes and the protection of workers from radiation. Of interest to physicians will be sessions on "General Aspects of Cancer Therapy" and "Radium and Roentgen Therapy" on Tuesday, October 29; and "Neutron and Artificial Radioactivity Therapy" on Thursday, October 31; "Dosage Measurements" and "Radiology" on Friday, November 1. Robley D. Evans, Ph.D., Massachusetts Institute of Technology, is chairman of the program, and members include Gioacchino Failla, D.Sc., of Memorial Hospital for the Treatment of Cancer and Allied Diseases, New York, and Ernest O. Lawrence, Ph.D., of the University of California, Berkeley.

Deaths in Other Countries

Dr. Julius Wagner-Jauregg, winner of the Nobel Prize in 1927 for his work in the use of malaria fever in treating paresis, died in Vienna, October 1, aged 83. Born in Wels, Upper Austria, March 7, 1857, Dr. Wagner-Jauregg made his medical studies in Vienna, receiving his degree of doctor in 1880. He was connected with the department of experimental pathology at Vienna from 1876 to 1882 and with the clinic in psychiatry from 1883 to 1889. He served as extraordinary professor of neurology and psychiatry in Graz from 1889 to 1893. In the latter year he returned to the University of Vienna as professor, serving until 1928 when he reached the retirement age. In 1887 there appeared his first work on the action of febrile diseases on the psychoses in which he recommended particularly the use of malaria. In 1917 he began his malarial injections for the treatment of progressive paralysis and other psychoses. His contributions to medical literature were numerous, including "Myxedema and Cretinism," a "Text-book of Organotherapy" and "Prevention and Treatment of Progressive Paralysis by Malaria Therapy." In 1938 an award of \$1,000 and a medal were presented to Dr. Wagner-Jauregg by the Committee on Research in Syphilis, an American committee, through the Austrian consul general at a special meeting in New York. In his honor, the name of the Vienna Neurologic Clinic was changed to the Wagner-Jauregg Clinic.

CORRECTIONS

Number of Doctors in Georgia.—In a medical economic abstract in the Organization Section of *THE JOURNAL*, September 28, page 1108, it was stated that in Georgia for the state as a whole there is one physician to 1,560 of population. According to the 1940 American Medical Directory, Georgia has a population of 3,073,000. The number of physicians is 2,825, thus giving Georgia one physician to 1,088 of population.

Number of Deaths from Asphyxiation.—In the article by Beck, Schulze and Suter entitled "Carbon Monoxide—A Domestic Hazard," in *THE JOURNAL*, July 6, an estimate of the number of deaths from asphyxia occurring annually in the United States was given as about 50,000. Mr. A. D. Battey, statistician of the National Safety Council, Inc., in Chicago, writes that, based on the U. S. Census Bureau Reports for 1938, it would seem that the total of accidental and suicidal deaths which might be classified as asphyxiation was in the neighborhood of 9,500, and if to this was included also the cases of drowning, the grand total would be only about 18,000. Dr. Beck states that he quoted the foregoing number from the *Ohio Health News* of May 1, 1937. A reply to an inquiry addressed to the Ohio State Department of Health stated that it was unable from the files to justify the statement which had been made in the *Ohio Health News* and that the persons who were responsible for the editing of that particular issue are no longer connected with the Ohio State Department of Health.

Government Services**Wellcome Prize Awarded to Captain Johnson**

The 1940 award of the Sir Henry S. Wellcome gold medal and a cash prize of \$500 have been made to Captain Lucius W. Johnson, medical corps, U. S. Navy. Competitors from the various branches of the government services were invited to present essays on the subject "Medical and Sanitary Care of the Civilian Population Necessitated by Attacks from Hostile Aircraft." The award will be presented at the annual meeting of the Association of Military Surgeons in Cleveland, October 10-12, and the prize essay will be published in the *Military Surgeon*, the official publication of this association. Captain Johnson's contributions to medical literature have been numerous. His awards have included the Navy Cross for relief work in Santo Domingo in 1930 and the Kober Prize and Lectureship on the subject of plastic surgery in 1936. Captain Johnson is under orders to serve as commanding officer of the navy's first mobile base hospital. Recently his duty has been to serve the bureau of medicine and surgery in an advisory capacity on hospital construction.

Microfilm Service of Army Medical Library

A new microfilm service has been established in the Army Medical Library in Washington, D. C. It will be conducted on a nonprofit basis solely for making the extensive medical literature collections of the Army Medical Library available to research workers who are unable to come in person to consult them. The library cooperates by providing the necessary space for the work and by supplying the publications from which the microfilm copies are made. The only cost to the user is for the actual labor and materials required in making and distributing the microfilm copies. The photographic copies on moving picture film of the separate articles in the periodicals are made at 30 cents for each complete article not exceeding thirty pages in length and ten cents for each succeeding ten pages or fraction thereof. A pamphlet describing the service and also containing the latest list of the approximately 4,000 medical and related periodicals currently received by this library will be sent to those desiring to avail themselves of this service. In addition to medical periodicals the library also possesses an extensive collection of manuscripts and incunabula of which microfilm copies may be obtained. Requests should be made to Microfilm Service, Army Medical Library, Seventh Street and Independence Avenue S.W., Washington, D. C. The new service was financed by a group of "Friends of the Army Medical Library." For nearly three years microfilm copying from the medical collections of the library has been conducted by Biblioform Service, a nonprofit agency having its headquarters in the library of the U. S. Department of Agriculture.

LONDON*(From Our Regular Correspondent)*

Aug. 31, 1940.

The Use of Sulfonamide Derivatives in the Army

The War Office has issued a memorandum on the use of the sulfonamide derivatives for the guidance of army medical officers, which, however, is of wider interest, for it has been compiled by the leading experts of the day and is the last word on the subject. It is recommended that sulfapyridine should be given in gonorrhea, cerebrospinal fever, pneumococcal infections, staphylococcal septicemia and gas gangrene. But as supplies are not unlimited, economy should be observed. Sulfanilamide should be the drug of choice in the prophylaxis of wound infection and the treatment of erysipelas, cellulitis, meningococcus carriers, the acute phase of wounds known to be infected with hemolytic streptococci, follicular tonsillitis, otitis media and *Bacillus coli* urinary infections. But sulfanilamide is inactive against all pneumococci excepting type III and has little action on staphylococci. The principle of effective treatment is to obtain a high blood concentration as rapidly as possible and to maintain this for a time. As the drugs are rapidly excreted, administration should be four hourly day and night. For maintaining a steady blood concentration the oral route is the best and should ordinarily be followed. But when swallowing is impossible, when gastric upset prevents absorption and in neglected cases in which no time must be lost a soluble preparation for injection is valuable. For established or developing infections, courses of treatment should seldom exceed ten days. A further course should be prescribed only in exceptional circumstances and with precautions against granulocytopenia. As a rule when infection is amenable to these drugs the result is rapid.

**INFECTIONS DUE TO STREPTOCOCCI AND
GAS GANGRENE BACILLI**

The earlier treatment is begun the more likely is it to prevent or control an acute infection, but benefit can be expected even in established infections. A prophylactic course of sulfanilamide should be given to all wounded persons who there is reason to fear may have septic infection or gas gangrene. This should be started as soon as possible and continued for at least four days to protect the patient against the risk of later infection by streptococci in the hospital. Prophylactic treatment may be administered orally or by local application to the wound. For established infections sulfanilamide or sulfapyridine may be used. For prophylaxis the first dose should be 1.5 Gm. of sulfanilamide. Two hours later four hourly administrations of 0.5 Gm. should begin and they should be continued for four days. If it is feared that gas gangrene is already beginning, the first two doses should be doubled.

For the treatment of gas gangrene and severe streptococcal infections the first dose of sulfanilamide or sulfapyridine should be 2 Gm. Subsequent doses, starting two hours later and continuing at four hourly intervals, should be 1 Gm. After two days, as the condition improves, the interval may be prolonged, but not to more than six hours for several days. After the temperature becomes normal small doses (3 Gm. daily) should be continued for three or four days.

MENINGOCOCCIC INFECTIONS

Groups I and II meningococci are equally susceptible to sulfonamide treatment. Early treatment and the maintenance of a concentration of 5 mg. per hundred cubic centimeters of the drug in the cerebrospinal fluid for the first three days and slightly less for a further five or six days is necessary. As

long as administration continues the intake of fluids should be approximately 4 pints (2,000 cc.) daily. Sulfapyridine is slightly more effective than sulfanilamide and has the advantage of being active also against pneumococci. The total dosage in the twenty-four hours should be 8 Gm. and in extreme cases up to a maximum of 10 Gm. On starting treatment the total twenty-four hour dose should be given in the first two administrations; it should then be given in equal doses every four hours. This is done for two or three days, after which the dose is gradually reduced over the next six days to 2 or 3 Gm. daily. In cases of vomiting or difficulty in swallowing, soluble sulfapyridine 1 Gm. should be given by intramuscular injection. In fulminating cases the same should be given plus an intravenous injection of 1 Gm.

PNEUMOCOCCIC INFECTIONS

In lobar pneumonia 5 Gm. of sulfapyridine should be given in the first twelve hours in lots of 2 Gm., 2 Gm. and 1 Gm. every four hours. This is followed by 1 Gm. every four, six or eight hours according to response. When vomiting renders absorption inadequate, soluble sulfapyridine 1 Gm. should be injected intramuscularly every four hours. For pneumococcic meningitis the procedures and dosage are the same as for meningococcic meningitis. It should be remembered that with a frankly purulent focus the drug is inactive and that the common causes of pneumococcic meningitis—otitis and mastoiditis—must be looked for and drained.

A Suspicious Use of Hospital Ships Not to Be Accepted

The repeated attacks on hospital ships, despite distinctive and unmistakable markings, has been described previously. Failure to respect the Red Cross has now been followed by an attempt to misuse it as a help in waging war. Through the Swiss government the British government has received notice that the German government proposes to use vessels distinguished by Red Cross markings for the purpose of rescuing airmen shot down into the sea. The British government has replied that, while it is willing to accord to hospital ships the immunities conferred on them by the Red Cross conventions, their use in a manner calculated to interfere with the conduct of naval and military operations cannot be admitted, especially in view of the attitude adopted toward British rescue boats saving both British and German airmen and the deliberate and flagrant attacks on British hospital ships. On July 12 the British government addressed a protest to Germany, through the medium of the United States government, on many deliberate attacks on British hospital ships, including the actual sinking of three, and no reply was received from the German government. The British government does not place its own boats, used for rescuing airmen, under the Red Cross although they have been repeatedly attacked. It does not feel justified in admitting the German pretensions in respect of vessels the character and function of which are in any case open to the gravest suspicion. It is calculated that six German airmen are brought down daily in the sea. For their rescue the Germans want to be allowed immunity for sixty-four so-called hospital ships.

Lung Injury in Intact Thorax

Though lung injury in intact thorax is familiar as a possibility to most surgeons, it has received little notice in surgical literature; it is often not diagnosed and is not mentioned in recent books on athletic injuries. Probably the first case recorded in English is that reported in the *Dublin Journal of Medical Science* by the surgeon R. W. Smith. A man was knocked down by a train, which passed over his body. He was admitted to the hospital with intense dyspnea and emphysema at the root of the neck. There was no hemoptysis and he died

three quarters of an hour later. The necropsy showed collapse of the right lung with extensive pneumothorax. A large quantity of blood was found around the roots of the great vessels and three lacerations in the substance of the lung, but no tear of the pleura was demonstrated. There were no fractured ribs. In the current number of the *British Journal of Surgery* Martin Fallon has reported the following case:

A medical student, aged 24, was knocked down three times in a boxing contest. An hour after the fight he felt sore in the small of the back and thought he had "pulled" a muscle. He went to bed but the pain prevented sleep and was aggravated by hiccup. On the following day he was strapped, which made him feel easier. On the third day after the fight he coughed up blood clot and was afraid to cough again. He was then seen by Fallon, who found only some bruising over the left lower ribs in front. Examination of the lungs was negative. On the following day he coughed up more dark clot. A roentgenogram showed a cavity containing fluid in the lower lobe of the left lung. No further hemorrhage occurred but yellowish green sputum was coughed up freely. Eleven days after the injury the cavity was smaller and the fluid had gone, and eighteen days afterward the cavity was barely distinguishable. Recovery was complete. As to the mechanism of this injury, it has been suggested by Gosselin that compression of the lung causes instinctive closure of the glottis, making it impossible for the pulmonary sponge to empty. The lung then bursts as a solid mass, like the spleen or liver.

Sir J. J. Thomson

Sir J. J. Thomson, F.R.S., the greatest living British physicist, the discoverer of the electron, has died at the age of 83 years. He was master of Trinity College, Cambridge, and professor of physics in the university. The Cavendish professorship was occupied in succession by Clerk Maxwell, Rayleigh, Thomson and Rutherford. No similar position was ever held by four men of such great and varied genius. In the early years of his professorship, which he attained at the early age of 27, Thomson was largely occupied in consolidating the electromagnetic theory left by Clerk Maxwell in his classic treatise. In 1893 he published "Recent Researches in Electricity and Magnetism," a kind of sequel to Maxwell's treatise. He was convinced that the next great advance in our knowledge of the relation between electricity and matter would be derived from a study of the phenomena which accompany the discharge of electricity through gases. He persisted in seeking evidence for his view that the carriers of the current in these discharges were positively and negatively charged ions formed by the disruption of the molecules of the gas. After the discovery of the x-rays in 1895 by Roentgen the mechanism of gaseous conduction was soon unraveled. But this was only the fringe of the matter. The researches of Hittorf, Crookes and others had shown that in high voltage electric discharges in rarefied gases radiation, called cathode rays, emanated from the negative pole and had various interesting properties. Among these it caused the walls of the glass bulbs used to glow with a greenish yellow light. There was some controversy as to the nature of this radiation. Thomson showed that it was a material projection of electrified atoms from the negative pole. He measured not only the speeds of the particles but also the proportion which the mass of a particle bears to its electric charge. The mass was proved to be a minute fraction of that of a hydrogen atom. This was a great advance, for the chemical atom had stood for nearly a century as an indivisible unit. It now appeared that there was a more fundamental unit—an atom of electricity, a constituent of all chemical atoms. This he originally called a corpuscle, later an electron. Thus he initiated the great revolution in modern physics and radio and photo-electricity.

Deaths

Thomas Hugh Scott, Oklahoma City; Central Medical College of St. Joseph, Mo., 1903; was commissioned as a passed assistant surgeon in the reserve of the United States Public Health Service Sept. 1, 1919, was promoted to surgeon, Nov. 19, 1919, and on March 17, 1921, was promoted to senior surgeon; on June 10, 1922, was detailed to the United States Veterans Administration and on July 25, 1922, was promoted to the rank of assistant surgeon general; commission expired on March 15, 1923, and on March 16, 1923, was given a commission as senior surgeon; was placed on inactive status, June 6, 1924, while still serving on detail with the Veterans Administration, and official status with the public health service ceased on that date; commission automatically expired March 15, 1928; for many years medical officer in charge of the Veterans Administration Facility, Hines, Ill.; aged 61; died, August 31, of cerebral hemorrhage.

Franklin Randolph Wright * Minneapolis; University of Minnesota College of Medicine and Surgery, Minneapolis, 1894; an Affiliate Fellow of the American Medical Association; clinical assistant in surgery and dermatology at his alma mater from 1896 to 1902, clinical instructor of dermatology and genito-urinary diseases from 1902 to 1909, assistant professor of genito-urinary diseases from 1909 to 1920, assistant professor in charge, division of urology from 1915 to 1920, associate professor and director, division of urology from 1920 to 1936 and since 1936 associate professor of urology emeritus; member of the American Urological Association; fellow of the American College of Surgeons; urologist to St. Barnabas Hospital; aged 74; died, August 1, of coronary thrombosis, hypertension and arteriosclerosis.

George W. Jacoby * New York; Friedrich-Wilhelms-Universität Medizinische Fakultät, Berlin, Prussia, 1877; Bellevue Hospital Medical College, New York, 1877; member and past president of the American Neurological Association; past president of the New York Neurological Association; consulting neurologist to the Lenox Hill and Beth Israel hospitals and the New York Infirmary for Women and Children; on the consulting staff of the Craig Colony for Epileptics; author of "Child Training as an Exact Science" in 1914 and "Physician, Pastor and Patient" in 1936; aged 83; died, September 11.

Allan Stuart * Medical Inspector, Commander, U. S. Navy, retired, Chatham, Mass.; Medical College of the State of South Carolina, Charleston, 1889; veteran of the Spanish-American War; entered the navy in 1900 and retired Oct. 1, 1923, on own application after thirty years' service; aged 75; died, August 18, in the United States Naval Hospital, Chelsea, of adenocarcinoma of the prostate.

George Barrow Worthington, San Diego, Calif.; Cooper Medical College, San Francisco, 1904; an Affiliate Fellow of the American Medical Association; fellow of the American College of Physicians; past president and secretary of the San Diego County Medical Society; served during the World War; at one time county health officer; aged 62; died, August 14.

Mathilde Loth * New York; Yale University School of Medicine, New Haven, Conn., 1922; on the staff of the Babies Hospital; pediatrician to the Vanderbilt Clinic; instructor in pediatrics at the Columbia University College of Physicians and Surgeons; aged 44; died, August 29, in the Mount Sinai Hospital of carcinoma of the breast with metastases.

Napoleon Strock Johnson, Clanton, Ala.; Medical College of Alabama, Mobile, 1901; member of the Medical Association of the State of Alabama; vice president of the Alabama Association of Railroad and Industrial Surgeons; formerly member of the city council; served during the World War; aged 57; died, August 30, of carcinoma of the bladder.

Fred E. Thompson, Detroit; Hahnemann Medical College and Hospital, Chicago, 1902; at one time city physician; fellow of the American College of Surgeons; formerly on the staff of St. Joseph's Mercy Hospital; aged 69; died, August 13, at his summer home at Lake of Bays, Ont., Canada, of coronary thrombosis and bronchopneumonia.

Fred L. Burdon, London, Ont., Canada; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1888; L. R. C. S., L. R. C. P., Edinburgh, and L. R. F. P. & S., Glasgow, Scotland, 1893; formerly member of the board of health and board of education; aged 85; died, August 26, in St. Joseph's Hospital.

Herman Theodore Schlegel * Wausau, Wis.; Chicago College of Medicine and Surgery, 1909; member of the American Academy of Ophthalmology and Otolaryngology; served

during the World War; aged 70; died, August 9, in the Memorial Hospital of acute myocarditis and cholelithiasis.

Arthur Augustus Whittemore, Wishek, N. D.; Minneapolis College of Physicians and Surgeons, 1903; member of the North Dakota State Medical Association; formerly state health officer; at one time member of the state board of education; aged 65; died, August 6, of carcinoma.

Norton Henry Good * Buffalo; University of Buffalo School of Medicine, 1905; on the staffs of the Charity Ear, Eye and Throat Hospital, Deaconess Hospital and the Lafayette General Hospital; aged 63; was drowned, August 24, while fishing at Crescent Beach, Ont.

Pleasant H. Askew Sr., Nashville, Ga.; University of Georgia Medical Department, Augusta, 1897; member of the Medical Association of Georgia; formerly mayor, member of the city council and school board; aged 67; died, August 12, in a hospital at Thomasville.

Raynor Elmore Holmes Sr., * Canon City, Colo.; Northwestern University Medical School, Chicago, 1901; formerly health officer; physician in charge of the Colorado State Penitentiary Hospital; aged 68; died, August 29, in the Corwin Hospital, Pueblo.

Roscoe Daniel Smith * Clarinda, Iowa; Drake University College of Medicine, Des Moines, 1909; member of the American Psychiatric Association; superintendent of the Clarinda State Hospital; aged 59; died suddenly, August 23, of coronary thrombosis.

Tenney Hall Wheatley, Brooklyn; University of Vermont College of Medicine, Burlington, 1896; for many years diagnostician for the New York City Department of Health; on the staff of the Victory Memorial Hospital; aged 72; died, August 4.

Earl Howard Marcum * Bemidji, Minn.; Hahnemann Medical College and Hospital, Chicago, 1903; served during the World War; aged 61; died, August 5, in the Lutheran Hospital of gas bacillus infection following an automobile accident.

Walter Leroy Misener, Richmond, Ind.; Physio-Medical College of Indiana, Indianapolis, 1901; member of the Indiana State Medical Association; veteran of the Spanish-American and World wars; aged 62; died, August 29, of angina pectoris.

Horace M. C. Grow, Yuma, Ariz.; University of Oregon Medical School, Portland, 1926; member of the Arizona State Medical Association; served during the World War; aged 47; died, August 20, in San Diego of acute dilatation of the heart.

William John Tindall, New York; University of Vermont College of Medicine, Burlington, 1897; formerly on the staff of the Neurological Institute; aged 71; died, August 27, in the Veterans Administration Facility of cerebral hemorrhage.

Charles Bernard Yott, Indianapolis; Indiana University School of Medicine, Indianapolis, 1929; member of the Indiana State Medical Association; on the staffs of St. Vincent's and Methodist hospitals; aged 35; was found dead, August 3.

Louis Freedman, Brooklyn; Cornell University Medical College, New York, 1903; member of the Medical Society of the State of New York; aged 65; died, August 28, in Lakewood, Pa., of hypertension and coronary thrombosis.

William A. L. McLister, Brighton, Tenn.; Vanderbilt University School of Medicine, Nashville, 1884; aged 78; died, August 14, in the Baptist Hospital, Memphis, of carcinoma of the prostate with retroperitoneal metastasis.

John B. Mathis, Ullin, Ill.; Barnes Medical College, St. Louis, 1900; member of the Illinois State Medical Society; aged 68; died, August 13, in St. Mary's Hospital, Cairo, of peritonitis secondary to perforated ulcer.

Anton F. Pav * Cleveland; Western Reserve University Medical Department, Cleveland, 1889; formerly on the staff of the City Hospital and St. Alexis Hospital; aged 70; died, August 10, of coronary thrombosis.

Herman Henry Rohwedder, Chicago; Illinois Medical College, Chicago, 1904; also a dentist; aged 67; died, August 26, in the Mercy Hospital, Davenport, Iowa, of arteriosclerosis, hypertension and edema of the lung.

Joseph Stanley Shinn, Troy, Ohio; Starling Medical College, Columbus, 1905; member of the Ohio State Medical Association; served during the World War; aged 61; died, August 20, of coronary thrombosis.

Elizabeth C. Earle, Grand Rapids, Mich.; Woman's Medical College, Chicago, 1884; formerly on the staff of the Butterworth Hospital; aged 83; died, August 29, of chronic myocarditis and cerebral sclerosis.

Peter Ferrini, Middleboro, Mass.; Harvard Medical School, Boston, 1927; member of the Massachusetts Medical Society; assistant superintendent of the Lakeville State Sanatorium; aged 39; died suddenly, August 5.

Francis Nicholis Maginnis, Aurora, Ill.; Chicago College of Medicine and Surgery, 1910; member of the Illinois State Medical Society; aged 68; died, August 10, in St. Charles Hospital of cerebral hemorrhage.

John Egbert Jennison ♂ San Diego, Calif.; University of Minnesota College of Medicine and Surgery, Minneapolis, 1894; aged 72; died, August 19, in the Mercy Hospital of hypostatic pneumonia and bulbar paralysis.

Walter Clarence Simmons, Smiths Grove, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1890; formerly mayor of Smiths Grove; aged 72; died, August 23, of acute dilatation of the heart.

Sarah Gardiner Pierson, Rochester, N. Y.; Syracuse University College of Medicine, 1903; formerly on the staff of the Rochester State Hospital; aged 63; died, August 26, of arteriosclerosis and chronic nephritis.

Douglas L. Gordon, Detroit; Michigan College of Medicine and Surgery, Detroit, 1900; member of the Michigan State Medical Society; aged 63; died, August 28, in the Harper Hospital of coronary occlusion.

Joseph Emerson Welborn ♂ Evansville, Ind.; Indiana University School of Medicine, Indianapolis, 1929; on the staff of the Welborn-Walker Hospital; aged 34; died, August 18, of acute dilatation of the heart.

Orien Lee Patrick Jackson, Union, S. C.; Emory University School of Medicine, Atlanta, 1893; member of the South Carolina Medical Association; aged 68; died, August 3, in the Wallace Thomson Hospital.

Elmer Alfred Pillon, Detroit; Detroit College of Medicine, 1910; on the staff of the Providence Hospital; aged 57; died, August 16, near Leamington, Ont., Canada, of injuries received in an automobile accident.

Allen Greenleaf Crow, Newark, Ohio; Ohio State University College of Medicine, Columbus, 1915; member of the Ohio State Medical Association; served during the World War; aged 49; died, August 5.

William James Reuter ♂ Ohio City, Ohio; Medical Department of the University of Cincinnati, 1913; for many years member of the board of health; aged 51; died, August 1, of cerebral hemorrhage.

Emil Edgar Hein, St. Louis; St. Louis University School of Medicine, 1914; member of the Missouri State Medical Association; aged 49; died, August 31, in St. Albans, Mo., of cerebral hemorrhage.

John Geddes Randall ♂ Missoula, Mont., Hahnemann Medical College and Hospital, Chicago, 1898; for many years president of the school board; aged 67; died, August 15, of coronary occlusion.

Watt Orr McDaniel, Streetman, Texas; Gate City Medical College, Texarkana, Ark., 1905; member of the State Medical Association of Texas; aged 67; died in August of carcinoma of the tongue.

Thad W. Shore, Boonville, N. C.; University College of Medicine, Richmond, Va., 1898; aged 64; died, August 16, in the North Carolina Baptist Hospital, Winston-Salem, of coronary disease.

Ulric Joseph Renaud, Brockton, Mass.; Medical School of Maine, Portland, 1919; member of the Massachusetts Medical Society; aged 43; died, August 12, in the Goddard Hospital of septicemia.

Charles Ralph Spicer, Hastings, Neb.; Rush Medical College, Chicago, 1896; member of the Nebraska State Medical Association; aged 70; died, August 19, of coronary thrombosis.

Thomas Rogers Hoge ♂ Wheeling, W. Va.; Jefferson Medical College of Philadelphia, 1923; aged 45; died, August 3, in the Ohio Valley General Hospital of seminoma of the testicle.

Robert Chester Grieve, Khartoum, Sudan, Africa; University of Oregon Medical School, Portland, 1938; aged 28; was killed, August 23, as the result of a machine gun attack.

John Wood Gordon ♂ Belle Vernon, Pa.; Jefferson Medical College of Philadelphia, 1878; aged 84; died, August 6, in the Allegheny Hospital, Pittsburgh, of myocarditis.

Frank Knight Lord, Richmond, Va.; University College of Medicine, Richmond, 1908; member of the Medical Society of Virginia; aged 60; died, August 18, of nephritis.

Henry G. Horstman ♂ Murphysboro, Ill.; Missouri Medical College, St. Louis, 1895; on the staff of St. Andrew's Hospital; aged 71; died, August 11, of coronary occlusion.

Austin Fisher Clarke ♂ Oakland, Calif.; Kentucky School of Medicine, Louisville, 1892; aged 68; died, August 18, in the Peralta Hospital of nephritis and endocarditis.

James Thomas Walker, Crowder, Miss.; College of Physicians and Surgeons, Baltimore, 1886; formerly mayor; aged 78; died, July 30, at the Lambert (Miss.) Hospital.

William Perry Collins, Colman, S. D.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1901; aged 65; died, August 28, in Brookings of acute appendicitis.

Carl Arthur Smith, Evanston, Ill.; Northwestern University Medical School, Chicago, 1932; aged 40; died, August 2, at the Evanston Hospital of organic heart disease.

Roy Herman McGuire, Medora, Ill.; Washington University School of Medicine, St. Louis, 1932; aged 33; was found dead, August 24, of cerebral hemorrhage.

Herbert Le Roy Ransom, Pittston, Pa.; University of Maryland School of Medicine, Baltimore, 1910; served during the World War; aged 64; died, July 22.

Alfred William Semmens, Sacramento, Calif.; College of Medical Evangelists, Los Angeles, 1915; aged 73; died, August 11, of carcinoma of the prostate.

Guy Howard Swearingen ♂ Sac City, Iowa; Drake University College of Medicine, Des Moines, 1911; aged 59; died, August 8, of cerebral hemorrhage.

Thomas J. Henslee, Newburg, Ky.; University of Louisville Medical Department, 1890; aged 79; died, August 9, of carcinoma of the prostate.

Karl Russell, Allensville, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1897; aged 65; died, August 14, of carcinoma of the face.

Charles H. Meldrim, Savannah, Ga.; University of Georgia Medical Department, Augusta, 1893; aged 72; died, August 14, of coronary occlusion.

William David Haas, Bunkie, La.; Jefferson Medical College of Philadelphia, 1887; aged 73; died, August 26, of coronary thrombosis.

De Willis Little, Appleton, Minn.; College of Physicians and Surgeons, Baltimore, 1883; aged 80; died, August 11, of coronary embolism.

John Collier Robison ♂ Salt Lake City; Tufts College Medical School, Boston, 1904; aged 64; died, August 18, of coronary occlusion.

Joe W. Neal, Walnut Cove, N. C.; College of Physicians and Surgeons, Baltimore, 1889; aged 76; died, August 2, of lobar pneumonia.

Donald Vincent Burns, Brooklyn; Long Island College Hospital, Brooklyn, 1928; aged 39; died, August 25, of cirrhosis of the liver.

Peter Hines Williams, Raleigh, N. C.; Leonard Medical School, Raleigh, 1901; aged 62; died, August 23, of coronary thrombosis.

N. H. Stone, Tazewell, Tenn.; Lincoln Memorial University Medical Department, Knoxville, 1906; aged 76; died, August 4, of uremia.

Joseph William Droogan ♂ New York; Albany (N. Y.) Medical College, 1891; aged 71; died, August 27, of heart disease.

Albert Edward Rogers ♂ Boston; Harvard Medical School, Boston, 1890; aged 72; died, August 8, of coronary thrombosis.

Steven George Harnden, Dalton, Ark. (licensed in Arkansas in 1903); aged 72; died, August 7, of heart disease.

Correction.—In the obituary notice of Dr. William Allen Pusey (THE JOURNAL, September 7, p. 872) it was stated that his grandfather was John T. Hodgen, former President of the American Medical Association. The actual relationship was as follows: "Dr. Pusey's father, Dr. Robert B. Pusey, married Belle Brown, daughter of Alfred M. Brown, who was the son of William Brown who settled in Kentucky in 1790. Alfred M. Brown had a sister who married Jacob Hodgen of Hodgenville, Ky. One of their children was John T. Hodgen, who became a physician and settled in St. Louis and later was made President of the American Medical Association. Actually, Dr. John T. Hodgen was a nephew of the grandfather of Dr. William Allen Pusey."

PREVENTION OF TUBERCULOSIS AMONG RECRUITS

To the Editor:—May I call your attention to what I consider a most important phase of the problem of medical preparedness? I refer to the problem of preventing tuberculosis in the vast army of young men now to be recruited.

As a member of the Committee on Military Affairs of the American College of Chest Physicians, I have given much thought to the tuberculosis problem facing us. One phase of this has already been sufficiently emphasized, namely that of how to prevent repetition of mistakes of the past war. As is well known, an enormous price had to be paid in cost and compensation to persons with old tuberculosis who were erroneously enlisted and became ill before reaching the front or even the training camps.

I am concerned with the far more important and much more difficult problem of preventing the development of fresh tuberculosis in young recruits. Unless we can work out a carefully planned and executed campaign of intensified tuberculosis prevention especially adapted to the present exigencies, we shall be facing the great threat of an epidemic-like occurrence of a newly developed and serious type of pulmonary tuberculosis among the youths of the army.

I am basing this prediction on the conclusions reached in a scholarly treatise recently written by Dr. Israel Rappaport on "Pulmonary Tuberculosis in the Present Epidemiologic Phase," which was presented before the Canadian Tuberculosis Association at its recent summer meeting in Montreal. Permit me to quote his conclusions here, as they will best explain:

We are now witnessing the evolution in our midst of what amounts to a practically new form of chronic pulmonary tuberculosis associated with the current changes in the epidemiology of tuberculosis. The chief characteristics of this new form of pulmonary tuberculosis we would state as follows:

1. Unlike classic phthisis it is of exogenous origin and exposure with its variations in intensity presumably plays a role in its development.
2. It occurs in individuals who at the time of exposure are not sensitive to tuberculin by our modern tests, although they have been infected with tuberculosis previously.
3. Compared with that of classic phthisis its onset is subacute or even acute and its course is far less chronic. It begins with a solitary infiltrative lesion and spreads at least at first chiefly by metastatic infiltrations, in contrast to classic phthisis, which issues from multiple nodular lesions and extends by craniocaudal progression of nodular lesions practically to its terminal phase.
4. It is the prevalent form of chronic pulmonary tuberculosis now in young adults, while classic phthisis is still the prevalent form of tuberculosis in the older age groups.
5. It is a considerably more progressive disease with a definitely higher fatality rate than that of classic phthisis.
6. It owes its evolution to the recent remarkable downward trend in the epidemiologic curve of tuberculosis, its incidence has been rising parallel with the descent of the latter and its features are readily explained from interpretations of the relationship between epidemiology, morbidity and mortality of tuberculosis.

War has always tended to raise the morbidity and mortality from tuberculosis. It seems to me that there is more to fear on this score than there was during the last war because of the recent remarkable shift in the epidemiology of tuberculosis, which left a vast proportion of our young people unprotected against exposure to tuberculosis which was well endured by the youth of a generation ago.

I believe that essentially the same fear is implied in the recent statement of Adamson:

We are on an immunological hotspot from which we dare not retreat for fear of disaster. It is generally agreed that it is safer to have a positive tuberculin reaction if one is to live in an infected atmosphere; since we are bringing up the younger generation with negative tuberculin reaction, we must provide an uninfected environment.

The army of young men which is now to be recruited from all sections of this country will naturally show the great differences in levels of tuberculinization which now exist between them (Frost). Perhaps the majority of these young men must now be expected to have negative tuberculin reactions and hence to be unprepared to meet contact in a new environment which is often likely to be a much overtuberculinized one in comparison to their home environment. Abrupt transition from a detuberculinized to a relatively overtuberculinized environment is the chief breeder of fresh serious pulmonary tuberculosis, particularly among young people. Recent experience with students of nursing and medicine in our hospitals should be interpreted as pointing definitely in this direction. It seems to me that these recent events might well be considered somewhat as a forerunner for that which I believe can be predicted to occur on a vastly multiplied scale among our youthful recruits. Special measures similar to those applied now in our schools of medicine and nursing should be taken in time to prevent the ravages of tuberculosis in our future army.

EDGAR MAYER, M.D., New York.

IMMUNITY TO TETANUS

To the Editor:—In reference to the editorial in *THE JOURNAL*, August 24, page 618, to the effect that "human beings do not acquire a demonstrable immunity against tetanus toxin as a result of environmental exposure," I wish to call attention to the article by TenBroeck and Bauer (Studies on the Relation of Tetanus Bacilli in the Digestive Tract to Tetanus Antitoxin in the Blood, *J. Exper. Med.* 37:479 [April] 1923), published from the Department of Pathology of Peiping Union Medical College, Peiping, China.

These investigators were interested in finding an explanation for the low incidence of tetanus in China, where approximately a third of the population is eliminating tetanus bacilli in the stool (TenBroeck, Carl, and Bauer, *J. H.: ibid.* 36:261 [Sept.] 1922) and where human feces are so generally distributed.

Their conclusions, based on titration studies, were that:

1. The serums of twenty-six persons who carried tetanus bacilli in the digestive tract all contained appreciable amounts of antitoxin.
2. The serums of thirty persons in whose stools no tetanus-like organisms were found were, with two exceptions, free from tetanus antitoxin.
3. Although we have been unable to measure accurately the antitoxin content of these human carriers of tetanus bacilli, 0.1 cc. of serum neutralizes ten or more minimum lethal doses of toxin, and it is evident that they have acquired an active immunity owing to the bacilli in the intestinal tract.
4. These results definitely prove that tetanus bacilli grow in the intestinal tract of man.
5. Many of the persons who have no tetanus bacilli in the intestinal tract and whose serum is free from antitoxin show agglutinins to tetanus bacilli. It is probable that they have been carriers of the bacilli in the past and that the agglutinins have persisted longer than the antitoxins. It seems likely, therefore, that these persons are potentially immune to tetanus.
6. If tetanus bacilli can be established in the digestive tract of man, we have a means of immunization which might be used in armies or in regions in which tetanus infections are common, though we do not recommend this method of immunization at present.

These writers reported the finding of antitoxin (0.1 cc. of serum neutralized at least ten minimum lethal doses of toxin) in fifteen of forty (37.5 per cent) specimens of serum picked at random from their Wassermann laboratory. This observation is of added interest because of the fact that in a previous study they had found that 34 per cent of seventy-eight persons in Peiping had tetanus bacilli in their stools.

The publication cited is of interest for two reasons: 1. It shows that environmental exposure to tetanus bacilli may stimulate the formation of antitoxin in the human body. 2. Support is given to the basic principle of immunization by way of the gastrointestinal tract. However, it is not to be concluded that active immunization by way of the gastrointestinal tract is either desirable or necessary. The feasibility of inducing active immunity by means of tetanus toxoid removes the necessity of resorting to peroral methods.

RALPH SPAETH, M.D., Chicago.

TREATMENT OF DIABETES

To the Editor:—In THE JOURNAL, September 21, page 1038, there appeared a letter concerning some of my remarks on the treatment of diabetes and diabetic emergencies made at a regularly scheduled conference on therapy held at the New York Hospital and Cornell University Medical College. The letter was signed by Drs. Joslin, Root, White and Marble. They disagreed with a number of the statements voiced and were emphatic in their criticism.

My outline in this conference was necessarily brief and was made to a group who understood that all the diabetic patients in our outpatient department were under periodic observation. All had been instructed in diets and many had been shown how to examine the urine for dextrose and acetone. Even though little attention is paid to glycosuria and high blood sugar at present, all the patients with glycosuria were seen every two or three weeks. This was done for two reasons: first, because we were so trained prior to the use of protamine zinc insulin and, second, because we noted no clinical deleterious effects of the glycosuria as reported by the patients who were receiving protamine zinc insulin. I agree with Drs. Joslin, Root, White and Marble that patients with severe (4 plus) ketosis should be sent to the hospital, and I regret that in my brief talk I failed to make that point clear. However, some of the patients who have been followed for months or years and who showed at times only a 1 or 2 plus acetone reaction in the urine were not sent to the hospital but were satisfactorily treated as outlined in my talk.

Dr. Joslin and his group have concentrated their attention on "two rather unusual patients" who were studied in detail in the Metabolism Ward of the Russell Sage Institute of Pathology, which has maintained the same careful technic and high standards in the study of patients since 1914. The results in these two cases were published in the *Archives of Internal Medicine* (64:91 [July] 1939). One of the statements made by Drs. Joslin, Root, White and Marble reads "It does not make common sense to say that an adult of average body build and activity receiving 1,640 calories daily in the form of carbohydrate 200, protein 75, fat 60 Gm. who is excreting 150 or even 100 Gm. of sugar in twenty-four hours, thus leaving a net balance of 1,040 or 1,240 calories respectively, could maintain body weight and be in nitrogenous equilibrium for a prolonged period." I cannot argue the point of whether or not "it makes sense." The facts published in detail in July 1939 clearly show that both patients studied did maintain their weights for from five to six weeks, the experimental period.

Then again Drs. Joslin, Root, White and Marble argue "Does it seem at all likely that the average diabetic patient will be symptomless while continuously excreting 10 per cent, or even 5 per cent, sugar?" Whether it seems likely or not, the patients studied were singularly free from symptoms on days when they did excrete 5 per cent and even 10 per cent of dextrose. I was just as dismayed at this turn of events as were Drs. Joslin, Root, White and Marble. Nevertheless such were my observations, and they were so recorded in all honesty.

The Boston group admits that the proof is lacking that hyperglycemia per se is damaging but insists on perpetuating "beliefs" and "implications" of its effect on infections and atherosclerosis.

Too much attention has been paid to glycosuria and high blood sugar, a carryover of the preinsulin era. With the use of protamine zinc insulin these criteria must be revamped as by the use of this hormone carbohydrate oxidation is assured for about a twenty-four hour period.

To advance, medicine in general and diabetes in particular must be based on firmly established facts obtained by recognized and reliable procedures. The metabolic experiment was done under carefully supervised conditions, the personnel was well trained and the data were most reliable. The results can be questioned only if and when the Boston group, repeating this experiment, obtains contradictory data. Then Drs. Joslin, Root, White and Marble will be in a position to challenge the facts. The Boston group believes in the orthodox treatment of diabetes. I myself am not much worried about the orthodox treatment of diabetes, as records show that orthodox views have changed at least once, and sometimes oftener, in each decade since 1914. From my work I am of the opinion that there may be more than one good method of treating diabetes and its complications ketosis and coma. Based on my experimental data I have extended the technic to the outpatient department, and the report of that work will appear shortly in the *Archives of Internal Medicine*, perhaps this month. I am proud that my views of these therapeutic conferences have extended beyond the walls of the New York Hospital and that they are criticized, because in our own institution my opinions are not shared by all the staff. I encourage this spirit, as I feel that only by frank expression of opinion and criticism, supported by established physiologic principles, can diabetes as well as other controversial medical treatment be placed on a sound basis free from beliefs, implications and traditions. I have great respect for the excellent work of my Boston colleagues. I am surprised, however, when they condemn a method of treatment based on stable experimental data and supported by good clinical results.

EDWARD TOLSTOR, M.D., New York.

"ELECTRICAL CONVULSION TREATMENT OF MENTAL DISORDERS"

To the Editor:—In the editorial in THE JOURNAL August 10 on "Electrical Convulsion Treatment of Mental Disorders" the only reference made concerning the technic is to the English article by Fleming. I should like to point out that the original technic, as utilized by Cerletti and Bini and as used in nearly all the clinics interested in the method, can be found in the English paper by McGregor and Shepley, *British Medical Journal*, Dec. 30, 1939, page 1269. These English workers first explained in detail the original technic. Fleming and his co-workers in their paper describe a technic differing from the original technic in various points, which, however, I do not wish to discuss in detail. In particular, they do not utilize the special electrodes which allow the application of a lower current intensity and a diminished time of passage of current necessary for the production of a seizure.

At the New York State Psychiatric Institute and Hospital, Dr. Kalinowsky and I have adhered to the original technic closely. We have been in constant touch with numerous clinics throughout the world engaged in this type of therapeutic procedure and from personal communications with these clinics we are able to say that several thousands of convulsions have already been produced with this method. It was just in light of the simplicity, the harmlessness and the effectiveness of the original method that we refrained from making any essential changes in the method. We also wish to recommend to American psychiatrists, with this original method, a simple technic which does not necessitate special knowledge of electrology and which may become a practical and useful routine treatment in psychiatric procedures.

S. E. BARRERA, M.D., New York.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

INDUSTRIAL NOISES AND EAR PROTECTION— ALKALI DERMATITIS

To the Editor:—I have recently made a survey of an industrial plant and found two conditions that I should like to correct. 1. About fifteen or twenty men are working in a department where they are exposed to excessive noise, such as steam pressure exhaust. This noise has a tendency to cause changes in the ear drum with acute occupational deafness. 2. There are a like number of men employed removing what they term reject, which is hot impurities from burning limestone. These particles strike them on the arms, hands and face and cause continued irritation with pustules which sometimes become infected. Can you suggest anything these men could use in the ears that would not cause irritation to the canal and any substance they could apply to the arms and face that would prevent the infection?

G. P. Morison, M.D., Charles Town, W. Va.

ANSWER.—1. Prior to the regular use of a device in the ears to protect workers against noises, effort should be made to eliminate the noises themselves if this is practical. In the present instance, for example, the offending steam exhaust pipe might be extended out of close proximity to the workers. In the absence of any such opportunities, some protection may be found in the wearing of "ear defenders," which are directly inserted into the external ear canal for a short distance. One type, marketed by the Mines Safety Appliances Company, provides insulation against approximately 80 per cent of air borne factory noises, in contrast to floor borne noises leading to conduction through the body. These ear defenders when inserted for the first few times may prove temporarily uncomfortable but, fitted properly and after being worn for a few days, are unlikely to prove disturbing. They do not interfere with ordinary conversation.

2. The hot impurities from limestone in addition to causing heat burns may lead to alkali dermatitis. Even though the particles themselves represent impurities and thus conceivably not quicklime; they are prone to be coated with lime dust, which is a well known source of alkali dermatitis. Alkali burns commonly are resistant to ordinary treatment, since usually a tenacious eschar is formed which acts as a foreign body and hampers recovery. By way of prevention of contact, some benefit may be derived from the application of a dense emollient material such as hydrous wool fat, containing mild acids or acid salts. Such a protective ointment, while likely to be of some benefit, usually fails as a complete source of protection. Commercial ointments protecting against alkalis are available. For safeguarding the eyes against alkalis, the wearing of tightly fitting light weight goggles may be necessary. In the type of work described high temperatures prevail, which stands in some relationship to the causation of skin disease, particularly in conjunction with alkali dust. Any temperature reductions may assume a helpful role in combating the dermatitis.

Alkali dust implanted around nail margins may not be removed by ordinary cleansing and may cause damage to nails and may favor secondary mycotic lesions. As a part of whatever protective measures are undertaken, scrupulous personal cleanliness is important.

GROWTH PROMOTING HORMONES

To the Editor:—A girl dwarf aged 8 has a mentality average of better than normal. Is it the type that anterior pituitary preparations would help if anything will. At what age should the preparations be given, what dose, and for how long a time? Is there danger of overstimulation to the sex organs if started too soon?

Copeland Bowers, M.D., Kokomo, Ind.

ANSWER.—The growth or somatotrophic hormone of anterior pituitary extracts is concerned with the general increase in body stature. Since other hormones, such as the gonadotropic and thyrotrophic hormones, of the anterior pituitary also have to do with growth, the term "growth hormone" is somewhat of a misnomer. Because it has a specific chondrotrophic action it has also been spoken of as a chondrotrophic hormone. Experimentally in animals this hormone has been shown to prevent epiphyseal closure. Hence therapy with such a preparation must be started as soon as possible. Clinically it has been shown that, the younger the patient, the more favorable is the result.

Pure preparations of the anterior pituitary growth hormone are not available, although not all of the preparations contain the thyrotrophic and gonadotropic fractions. Oral administration does not give consistent results, and the usual mode of administration is by intramuscular injection. The dosage varies from 0.5 to 1 cc. three times a week to 0.5 to 2 cc. daily. Frequent small doses are believed to be better than larger doses injected at longer intervals. If the dosage is adequate an increase in the rate of growth will appear within two to four months. However, cessation of treatment usually results in a decreased rate of growth, and hence the treatment must be continued until the optimal stature has been reached or the femoral epiphyses have united. If epiphyseal union has occurred before treatment is begun, no improvement in stature need be expected; nonunion can be demonstrated by x-ray examination.

Because the gonadotropic hormone in anterior pituitary extracts is sometimes credited with inducing an early epiphyseal closure, some investigators prefer to use a preparation which is free from this principle. Overstimulation of the sex organs following injections of an extract containing more than the growth hormone is held to be of secondary importance, as cessation of the injections will usually cause a regression of the sexual characters to the stage at which they should be for that age.

In addition to receiving anterior pituitary extracts, the patient should receive vitamin containing preparations such as cod liver or halibut liver oil and yeast preparations. Some clinicians have reported favorable results following the oral use of thyroid even though no evidence of hypothyroidism is present.

The fact that the patient to whom the inquirer refers has a mentality rating of average would tend to suggest an investigation for an existing achondroplasia. This condition may be determined by x-ray examination of the epiphyseal ends of the long bones.

DYSTONIA MUSCULORUM DEFORMANS

To the Editor:—A white woman aged 22 has dystonia musculorum deformans. I have tried in every way to control muscular movements but to no avail. Recently I used quinine with slight improvement. I have been told to try curare on this patient. Can you give me any information as to where I can obtain the drug, how it is administered and how often and for how long it may be given? I would appreciate a bibliography on the use of curare in the treatment of dystonia. M.D., New York.

ANSWER.—Treatment of dystonia musculorum deformans with curare has been carried out by Dr. M. S. Burman of New York. He obtained his preparation from Merck & Co., Inc., but so far as known the preparation has never been on the open market in this country and been used only experimentally, under strict supervision. It is believed that small quantities for experimental purposes may also be available from E. R. Squibb and Sons. The drug is one presenting considerable danger from overdosage. It has also been used experimentally in England by Dr. Ranyard West, although not specifically for dystonia musculorum deformans. Its pharmacologic action on the end plates of the motor nerves has been well known in physiology since the original experiments by Claude Bernard in 1865, and it is now well accepted that the peripheral paralysis caused by curare is due to a blocking of the nervous impulses at the myoneural junction. In doses not sufficient to cause actual paralysis, relaxation of muscular action has been observed by West, Burman and others.

The dosage, according to Burman, varies from patient to patient and depends on the weight of the individual and the extent of the muscular rigidity. Curare may be administered either intramuscularly or intravenously, and the average dystonic patient requires 25 mg. intravenously. Rarely has a larger dose than this been given, although as much as 40 mg. can be used intramuscularly. The effects usually last about two days. After treatment has been well established through a period of a number of weeks, Burman gave 30 mg. intravenously once a week. This appeared to be adequate to maintain the improvement.

The immediate effects of the injection in one patient are described by Burman as follows: The patient noticed a feeling of looseness in the muscles. The spasms tended to return at longer intervals and with less intensity than before injection. Previously unable to walk alone, the patient was able to do so after the injection, although she could not sustain a correct position for any amount of time. She could, however, pick up a glass of water and drink it, a movement that she had not been able to accomplish for several years. Other cases showed like improvement. Burman warns against the indiscriminate use of this powerful drug and suggests that other measures be also considered in the treatment of dystonia musculorum deformans. Mention is made of Putnam's results

of treatment by section of the extrapyramidal tracts of the spinal cord. It should also be noted that Hassin recently has reported on the effect of quinine in this disease, showing that large doses of this drug are decidedly beneficial. An exhibit of charts, photographs and motion pictures showing the collection of curare, the preparation of alcoholic extracts, the pharmacologic action and certain clinical features of the drug was presented as a scientific exhibit by Drs. A. E. Bennett, A. R. McIntyre and A. L. Bennett at the annual session of the American Medical Association in New York in 1940.

PULMONARY EMBOLISM

To the Editor:—I was much impressed by de Takats and Jesser's article on "Pulmonary Embolism" in *The Journal*, April 13. There are two obscure points on which I would appreciate enlightenment. It is said that "two clearcut pulmonary infarcts from a well localizable source would prompt us again to expose the iliac vessels." Would this be for the purpose of ligation of an iliac vein or extraction of the thrombus through the saphenous vein? Again, "ligation of the hypogastric or common iliac veins in septic thrombosis . . . has limitations which have been the subject of previous controversy." In an instance of repeated embolism I was able to ligate the external iliac vein with a satisfactory outcome. (*Am. J. Surg.* **45**: 145 [July] 1939). Will you please indicate the objections to ligation of the external, internal or common iliac veins respectively for thrombosis and embolism? Is not an attempt to extract a thrombus through the saphenous vein likely to cause separation of the thrombus and further embolism?

K. P. A. Taylor, M.D., Panama.

ANSWER.—Dr. de Takats replies: "Following two clearcut pulmonary infarcts I feel that a ligature above the thrombus is definitely indicated. My remark in regard to the ligature of the common iliac in septic thrombophlebitis refers to the old controversy which has raged in the obstetric literature with regard to its value in puerperal sepsis. Our gynecologists and obstetricians have felt that this operation was unable to prevent septicemia but the reports of Bancroft and Neuhof have been so encouraging that I quite recently planned to do one of these.

"I think there is a great deal in what the correspondent says against extracting the clot through an opening in the saphenous. Contrary to usual belief, however, the pressure in the femoral vein is positive and the brisk bleeding would expel the clot. I would do it again only in quite recent clots when the clot is soft and can readily be removed."

SULFANILAMIDE AND AZOSULFAMIDE

To the Editor:—I have been informed that neoprontosil (azosulfamide) has one-tenth the toxicity of sulfanilamide. Is this true? M.D., Texas.

ANSWER.—Some workers have reported that toxic reactions following the use of azosulfamide have been less in number and severity than when sulfanilamide is used but others claim that there is only a slight difference. Complete information on the relative toxicity has not been obtained because of variation among the species of animals used for experimental work and because the results obtained in the lower animals do not necessarily hold true for man. Many investigators believe that reduction of azosulfamide takes place in the tissues to release sulfanilamide as the active agent, while others are not so certain that this fully explains the activity of azosulfamide. The latter group does admit, however, that such a reduction probably plays a major part. The comparative lack of toxicity of azosulfamide may then be more apparent than real because (1) relatively small amounts of free sulfanilamide are released in the body and (2) the drug is rapidly eliminated from the body, from 85 to 95 per cent appearing in the urine within five hours after administration.

Although azosulfamide is considered by some to be as efficacious as sulfanilamide, Long and Bliss (*The Clinical Use of Sulfanilamide and Sulfapyridine and Allied Compounds*, New York, Macmillan Company, 1939) point out that, weight for weight, sulfanilamide should be six times as efficient as azosulfamide if sulfanilamide is the active agent in azosulfamide. Mellon, Gross and Cooper (*Sulfanilamide Therapy of Bacterial Infections*, Springfield, Ill., and Baltimore, Charles C. Thomas, 1938) also report that recent studies prove sulfanilamide to be superior therapeutically to azosulfamide. "Neoprontosil" has not been accepted to date by the Council on Pharmacy and Chemistry.

DEMENTIA PARALYTICA AND COAL MINING

To the Editor:—A man has been referred to me for an opinion as to the hazard involved in his returning to work as a coal miner. He has cerebrospinal syphilis. He was in a state hospital for the insane for fifteen months for dementia paralytica. He was discharged with a statement from the institution stating that he was apparently cured. His general condition now is good and he wishes to return to work. He is 47 years old. The blood pressure is 138 systolic, 84 diastolic. The blood Kahn reaction is positive. The spinal fluid Wassermann reaction is 0.1 four plus, 0.2 four plus, 0.5 four plus. He has no apparent dementia now. The deep reflexes are exaggerated. The pupils react to light and in accommodation. There is no Romberg sign. Please give me an opinion as to the hazard of his returning to work.

M.D., Illinois.

ANSWER.—From the information provided, it is not possible to make a specific recommendation concerning the advisability of this particular patient returning to his hazardous occupation. There are general principles, however, consideration of which make possible accurate decision as to the advisability of return to employment. In the first place, the period of time after apparent recovery from a parietic psychosis is of extreme significance. If the patient in question really had dementia paralytica and recovered after fifteen months of hospitalization, it is fair to assume that he was treated with malaria or some other form of fever. If this assumption is correct, his prospects for a normal future as time passes increase exactly as time passes, i. e. the longer after apparent recovery from a parietic psychosis he maintains a normal status, the greater the chance that that status will be maintained. If the patient has maintained a normal status for five years his prospects for the future are good.

These comments relate to the status of the patient himself, without reference to his occupation. If the occupation involves hazard only to himself, it may be judged accordingly. On the other hand, if his occupation involves the necessity for action or judgment which may jeopardize the safety or lives of other people, the question is different and return to it should be forbidden.

PICROTOXIN AND BARBITURATE POISONING

To the Editor:—What is the largest total amount of picrotoxin used in the treatment of patients with barbiturate poisoning who recovered? I am interested chiefly in reported cases, excluding the communication by Rovenstine in 1938 to the Council on Pharmacy and Chemistry.

M.D., Massachusetts.

ANSWER.—The literature contains close to thirty cases of barbiturate poisoning treated with picrotoxin. Recovery occurred in most of them. References are given in a Report of the Council on Pharmacy and Chemistry (*THE JOURNAL*, Feb. 4, 1939, p. 431). One of the largest doses of picrotoxin reported is that of a person who recovered after taking probably 671 mg. given intramuscularly over a period of four days (Kohn, Richard; Platt, S. S., and Saltman, S. Y.: *The Picrotoxin-Barbiturate Antagonism*, *THE JOURNAL*, July 30, 1938, p. 387). This antidote was not administered until six days after an unknown dose of phenobarbital had been taken. The patient also received apomorphine, oxygen, dextrose solution intravenously, caffeine, nikethamide, strychnine, atropine, strophanthin and ascorbic acid. In another case reported by the same authors 228 mg. was administered intravenously and intramuscularly within twenty-seven hours to a patient who took 100 grains (6.5 Gm.) of barbital and 10 grains (0.65 Gm.) of pentobarbital and recovered. In the first case all the drug was given intramuscularly, in the second mostly by vein.

The largest dose of picrotoxin given in any case of barbiturate poisoning is probably that of E. A. Rovenstine (*Am. J. M. Sc.* **196**: 46 [July] 1938) to which the writer refers. This patient took 500 grains (32.5 Gm.) of barbital and showed signs of recovery with each injection of picrotoxin up to a total of 2,134 mg. but finally had convulsions and succumbed on the eighth day to hypostatic pneumonia and acute hepatitis.

The amount of picrotoxin which may be prudently injected to antagonize a barbiturate depends on the dose of the latter. Large nonfatal doses of the hypnotic are likely to tolerate the largest amounts because of the physiologic antagonism between the two drugs. Small nonfatal doses are likely to respond with rigidity and convulsions even to small doses of picrotoxin. With doses of barbiturate in and above the fatal range, it may be expected that small doses of picrotoxin will prolong the course as much as heroic doses, which may even hasten respiratory failure. Kohn, Platt and Saltman pointed out that picrotoxin convulsions are followed by increased depression and that it is safer simply to increase the picrotoxin injections to the point of spontaneous movements. To reach this stage they recommend repeated intravenous injections; to sustain it, intramuscular administration.

EFFECT OF PNEUMONIA AND SULFAPYRIDINE
ON ASTHMA

To the Editor:—In January 1940 I treated a man aged 65 for type VI pneumonia with sulfapyridine. The same patient has been suffering for twenty-five years with bronchial asthma. The asthmatic attacks have been severe, especially in the hot summer days with paroxysmal dyspnea, which has been intense and suffocative. These attacks are relieved by smoking a mixture of belladonna and stramonium leaves. However, this summer the patient did not have any attacks in spite of the hot weather and appears comfortable nor does he show any signs of dyspnea. I should like to attribute this to a change in allergy as a result of the pneumonia treatment with sulfapyridine. My question now is whether any other medical men have had the same experience. Would you also advise me to treat other persons who have bronchial asthma with sulfapyridine?
M.D., New York.

ANSWER.—There are two possible explanations for the relief from attacks of asthma in this patient. It has been known for many years that fever of any sort frequently brings about a temporary cessation of allergic symptoms, e. g. asthma, hay fever, urticaria and allergic rhinitis. When an asthmatic person develops pneumonia or a severe infection of the upper respiratory tract, malaria or any other febrile condition, the asthma is apt to disappear in whole or in part. A large carbuncle can bring about a similar improvement. But, sooner or later, in from a week to a year or perhaps longer, symptoms almost invariably return. Because of this fact, fever therapy has been tried, with conflicting results, in many allergic individuals. This explanation is probably the correct one. The fact that this patient improved so startlingly after pneumonia would suggest that some form of fever therapy might well be tried later if symptoms should return.

Sulfapyridine has been tried in bronchial asthma but its use is so recent that authentic reports are not available. Asthma is a condition which tends to recur and no reports regarding the efficacy of various procedures are of much value until a year or more has elapsed after the treatment has been started. Asthma in many cases is influenced and perhaps even caused by bacteria. The role of bacteria in allergy is extremely debatable. Perhaps sulfapyridine or a related chemical may help by killing bacteria in the bronchial tubes. To date the results from its use in asthma are not too good, but it would seem well worth while to try out all these drugs in the various allergic conditions. The experiments should of course be well controlled.

INCREASED BLOOD PRESSURE AFTER HEAT
EXHAUSTION

To the Editor:—I have under my care a patrolman aged 46 with a blood pressure reading of 160/90 prior to August 8. On August 8 while on patrol duty he was overcome by the heat of the sun. He complained of dizziness and headache and had signs of general prostration. Since that date his blood pressure has been systolic 180-220 and diastolic 120-150. I would appreciate it if you would give me any information concerning the effects of the sun on blood pressure. Is it possible that the effects of the sun would give an elevation of blood pressure?
M.D., New Jersey.

ANSWER.—The question does not make clear whether the reading of the arterial tension at 160/90 was an isolated single observation or representative of the average level prior to the heat prostration. The difference is significant in interpreting the subsequent changes; a single observation may easily be grossly misleading by either temporary depression or transient elevation of the arterial tension from habitual levels. In the spastic phase of hypertensive disease, wide fluctuations between different observations are the rule. It is therefore possible that the heat prostration has had no real effect on the patient's arterial tension.

The effects of the sun as described are those of excessive heat. Heat exhaustion varies greatly in severity. In the more severe cases with hyperpyrexia the mortality is high, especially among older persons and those with preexisting disorders. Alcoholism greatly increases the injury and risk from exposure to excessive heat. The more common sequels of heat exhaustion include headache, vertigo, impairment of memory, hemiplegia and paraplegias. The most conspicuous pathologic manifestation in the brain is edema, but small hemorrhages are not rare (McKenzie, Pierce, and LeCount, E. R.: Heat Stroke, *THE JOURNAL*, July 27, 1918, p. 260). With preexisting hypertension the probability of cerebral vascular accident is enhanced. The dehydration which is a conspicuous phenomenon of acute heat prostration is a source of renal injury. Renal insufficiency frequently follows when nephritis exists prior to the heat exhaustion and some evidence of renal injury is the rule.

Though exacerbation of hypertension is usually not enumerated as one of the more common consequences of heat prostration, it is clear that there are two possible mechanisms by which such a sequel may arise: cerebral edema and/or hemorrhage and renal

injury with exacerbation of functional impairment. Neurologic and renal functional study of the patient are indicated to determine which of these mechanisms is responsible or whether both are involved.

CORONARY DISEASE AND PAPAVERINE

To the Editor:—What is the status of the use of papaverine in coronary disease? With the dosage of one-third grain (0.02 Gm.) of papaverine hydrochloride twice daily, how long could this therapy be maintained without cumulative effects?
M.D., New York.

ANSWER.—Little use has been made of papaverine in coronary disease. Its chief therapeutic application in circulatory disease has been in the attempt to produce peripheral vasodilatation. In cases of peripheral vascular disease papaverine hydrochloride can be given intravenously in the dose of one-fourth grain (0.016 Gm.) or even up to one-half grain (0.03 Gm.) dissolved in salt solution twice a day. In experimental animals papaverine has been shown to increase the coronary circulation, probably through vasodilatation. The blood pressure falls. Twenty-five years ago it was recommended for hypertension and angina pectoris as well as many other conditions but it has never gained popularity, probably because of its relative inactivity. Levy does not mention it in his chapter on the medical treatment of coronary disease and angina pectoris in the authoritative volume on diseases of the coronary arteries and coronary pain published by the Macmillan Company in 1936. White mentions it as having been suggested and tried in hypertension but does not speak of its use in coronary disease.

ALCOHOLIC INTOXICATION OR TOBACCO
POISONING

To the Editor:—I have been called to testify in the case of a man charged with drunken driving, who denies having had anything alcoholic to drink preceding his arrest for poor control of his car. The officer arresting him says the odor of alcohol was on his breath, but no physician examined him. The defendant claims that he accidentally swallowed a plug of tobacco, which he occasionally chews, after which everything got black and he knew nothing until the awakening in jail. There was no nausea or vomiting. Could swallowing this tobacco cause symptoms similar to alcoholism?
Alvin A. Rosenberg, M.D., Morristown, N. J.

ANSWER.—The swallowing of tobacco may produce facial flushing or pallor, pupillary dilatation or constriction, general muscular weakness and vertigo resulting in unsteady gait or impaired driving, even in habitual users of tobacco. Nausea and vomiting, however, would be expected. The odor of alcohol should not be confused with, though it may be masked by, tobacco and other substances. If the man was not actually stuporous or comatose, later amnesia rather than unconsciousness, accounting for his story, would also suggest alcoholism rather than tobacco poisoning. Detailed analysis of the officer's observations might indicate whether motor incoordination or impaired judgment was present, characteristic of alcoholic intoxication. The use of one of the chemical tests for intoxication, however, would have been particularly valuable in differentiating these conditions.

OBESITY AND MANGANESE DIOXIDE

To the Editor:—Would you please give me a little information on the safety and efficacy of manganese dioxide as an aid in the treatment of obesity? Is there any danger of manganese poisoning? I have been using just a little in 5 grain (0.3 Gm.) doses three times daily.
M.D., Illinois.

ANSWER.—No evidence for the rationale or recognized application of manganese dioxide in the treatment of obesity has been found. No reference to it has been obtained in the medical literature.

There appears to be little danger of manganese poisoning when the material is taken by mouth, chiefly because its absorption from the gastrointestinal tract is slight. Manganese poisoning does occur rather rarely as an occupational disease, in individuals exposed to the dusts of manganese compounds. In these cases the absorption is partly by inhalation. The symptoms of poisoning are primarily those of central nervous system involvement.

A review of the subject by W. F. von Oettingen of the Department of Pharmacology, Western Reserve University School of Medicine, will be found in *Physiological Reviews* 15:175 (April) 1935.

Medical Examinations and Licensure

COMING EXAMINATIONS

NATIONAL BOARD OF MEDICAL EXAMINERS EXAMINING BOARDS IN SPECIALTIES

Examinations of the National Board of Medical Examiners and Examining Boards in Specialties were published in *THE JOURNAL*, October 5, page 1219.

BOARDS OF MEDICAL EXAMINERS

ALABAMA: Montgomery, June 17-19. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

ARKANSAS: * Regular. Little Rock, Nov. 7-8. Sec., Dr. D. L. Owens, Harrison, *Eclectic*. Little Rock, Nov. 7. Sec., Dr. Clarence H. Young, 1415 Main St., Little Rock.

CALIFORNIA: *Oral examination* (required when reciprocity application is based on a state certificate or license issued ten or more years before filing application in California), Los Angeles, Dec. 11. *Written examination*. Sacramento, Oct. 21-24. Sec., Dr. Charles B. Pinkham, 1020 N St., Sacramento.

CONNECTICUT: * *Written*. Hartford, Nov. 12-13. *Endorsement*. Hartford, Nov. 26. Sec., Dr. Thomas P. Murdock, 147 W. Main St., Meriden. *Homeopathic*. Derby, Nov. 12-13. Sec., Dr. Joseph H. Evans, 1488 Chapel St., New Haven.

DELAWARE: July 8-10. Sec., Medical Council of Delaware, Dr. Joseph S. McDaniel, 229 S. State St., Dover.

DISTRICT OF COLUMBIA: * Washington, Nov. 11-12. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

FLORIDA: * Tampa, Nov. 18-19. Sec., Dr. W. M. Rowlett, Box 786, Tampa.

HAWAII: Honolulu, Jan. 8-11. Sec., Dr. James A. Morgan, 48 Young Building, Honolulu.

INDIANA: Indianapolis, June 17-19. Sec., Board of Medical Registration and Examination, Dr. J. W. Bowers, Citizens Trust Bldg., Fort Wayne.

IOWA: Des Moines, Dec. 9-11. Dir., Division of Licensure and Registration, Mr. H. W. Greffe, Capitol Bldg., Des Moines.

KANSAS: Topeka, Dec. 10-11. Sec., Dr. J. F. Hassig, 905 N. Seventh St., Kansas City.

KENTUCKY: Louisville, Dec. 3-5. Sec., State Board of Health, Dr. A. T. McCormack, 620 Third St., Louisville.

MAINE: Portland, Nov. 12-13. Sec., Board of Registration of Medicine, Dr. Adam P. Leighton, 192 State St., Portland.

MARYLAND: *Regular*. Baltimore, Dec. 10-13. Sec., Dr. John T. O'Mara, 1215 Cathedral St., Baltimore. *Homeopathic*. Baltimore, Dec. 10-11. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MASSACHUSETTS: Boston, Nov. 12-14. Sec., Board of Registration in Medicine, Dr. Stephen Rushmore, 413-F State House, Boston.

MINNESOTA: * Minneapolis, Oct. 15-17. Sec., Dr. Julian F. Du Bois, 350 St. Peter St., St. Paul.

MISSISSIPPI: *Reciprocity*. Jackson, December. Asst. Sec., State Board of Health, Dr. R. N. Whitfield, Jackson.

MISSOURI: Kansas City, Oct. 29-31. Sec., State Board of Health, Dr. Harry F. Parker, State Capitol Bldg., Jefferson City.

NEVADA: *Reciprocity* with oral examination, Nov. 4. Sec., Dr. Fred M. Anderson, 215 N. Carson St., Carson City.

NEW HAMPSHIRE: Concord, March 13-14. Sec., Board of Registration in Medicine, Dr. T. P. Burroughs, State House, Concord.

NEW JERSEY: Trenton, Oct. 15-16. Sec., Dr. Earl S. Hallinger, 28 W. State St., Trenton.

NORTH CAROLINA: *Reciprocity*. Durham, Dec. 3. Sec., Dr. W. D. James, Hamlet.

NORTH DAKOTA: Grand Forks, Jan. 7-10. Sec., Dr. G. M. Williamson, 4½ S. Third St., Grand Forks.

OKLAHOMA: * Oklahoma City, Dec. 11. Sec., Dr. James D. Osborn Jr., Frederick.

OREGON: * *Reciprocity*. Portland, October. *Written*. Portland, Jan. 14-16. Exec. Sec., Miss Lorraine M. Conlee, 608 Failing Bldg., Portland.

PENNSYLVANIA: Philadelphia, January. Acting Sec., Bureau of Professional Licensing, Miss Marguerite G. Steiner, 358 Education Bldg., Harrisburg.

SOUTH CAROLINA: Columbia, Nov. 12. Sec., Dr. A. Earle Boozer, 505 Saluda Ave., Columbia.

SOUTH DAKOTA: * Pierre, Jan. 21-22. Dir., Medical Licensure, Dr. J. F. D. Cook, Pierre.

TEXAS: Austin, Nov. 25-27. Sec., Dr. T. J. Crowe, 918-920 Mercantile Bldg., Dallas.

VERMONT: Burlington, Feb. 11. Sec., Dr. W. Scott Nay, Underhill.

VIRGINIA: Richmond, Dec. 4-6. Sec., Dr. J. W. Preston, 30½ Franklin Rd., Roanoke.

WEST VIRGINIA: Morgantown, Oct. 31-Nov. 2. Sec., Public Health Council, Dr. Arthur E. McClue, State Capitol, Charleston.

WISCONSIN: * Madison, Jan. 14-17. Sec., Dr. H. W. Shutter, 425 E. Wisconsin Ave., Milwaukee.

* Basic Science Certificate required.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

ARKANSAS: Little Rock, Oct. 21. Sec., Mr. Louis E. Gebauer, 701 Main St., Little Rock.

CONNECTICUT: New Haven, Oct. 12. Address State Board of Healing Arts, 1945 Yale Station, New Haven.

DISTRICT OF COLUMBIA: Washington, Oct. 21-22. Sec., Commission on Licensure, Dr. George C. Ruhland, 203 District Bldg., Washington.

FLORIDA: Gainesville, Nov. 1. *Applications must be on file not later than Oct. 16*. Sec., Prof. J. F. Conn, John B. Stetson University, DeLand.

OKLAHOMA: Oklahoma City, Nov. 18. Sec. of State, Hon. C. C. Childress, State Capitol, Oklahoma City.

OREGON: Portland, Oct. 26. Sec., Mr. Charles D. Bryne, State Board of Higher Education, University of Oregon, Eugene.

RHODE ISLAND: Providence, Nov. 20. Acting Chief, Division of Examiners, Mr. E. Clyde Thomas, 366 State Office Bldg., Providence.

SOUTH DAKOTA: *Examination*. Yankton, Dec. 6-7. *Endorsement*. Dec. 21. Sec., Dr. Gregg M. Evans, Yankton.

Alabama June Report

Dr. J. N. Baker, secretary, Alabama State Board of Medical Examiners, reports the written examination for medical licensure held at Montgomery, June 18-20, 1940. The examination covered ten subjects and included 100 questions. An average of 75 per cent was required to pass. Twenty-six candidates were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Howard University College of Medicine.....	(1937)*		79.9
Emory University School of Medicine.....	(1940)*	83.1,	90.5
Northwestern University Medical School.....	(1940)*		84.8
Rush Medical College.....	(1940)*	87,	88.3
Louisiana State University School of Medicine.....	(1940)*		82.2
Tulane University of Louisiana School of Medicine....	(1939)*		83.4,
(1940)*	86.9, 88.7, 88.8,	91.5, 91.8,	93.1
Harvard Medical School.....	(1936)*		82.2, (1940)*
Long Island College of Medicine.....	(1938)*		88.2
New York University College of Medicine.....	(1940)*		85.2
University of Pennsylvania School of Medicine.....	(1940)*		89.7, 92.3
Medical College of the State of South Carolina.....	(1940)*		84.6,
89, 89.4			
Vanderbilt University School of Medicine.....	(1940)*		87.5, 88.2

* Licenses have not been issued.

Delaware July Report

Dr. Joseph S. McDaniel, secretary, Delaware State Board of Medical Examiners, reports the written examination for medical licensure held at Dover, July 9-11, 1940. The examination covered ten subjects and included 100 questions. An average of 75 per cent in each subject was required to pass. Fifteen candidates were examined, all of whom passed. One physician was licensed to practice medicine by reciprocity. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
College of Medical Evangelists.....	(1940)		83.1
Hahnemann Medical College and Hospital of Phila.....	(1937)		85.4,
(1939)	82.7, 83.2		
Jefferson Medical College of Philadelphia.....	(1938)		82.6,
(1939)	84.2, 84.4, 87.8		
Temple University School of Medicine.....	(1934)	85, (1938)	79.5,
85.2, (1939)	80		
University of Pennsylvania School of Medicine.....	(1938)		79.5
Woman's Medical College of Pennsylvania.....	(1935)		81
University of Tennessee College of Medicine.....	(1938)		78.1

Minnesota June Report

Dr. Julian F. Du Bois, secretary, Minnesota State Board of Medical Examiners, reports the written examination for medical licensure held at Minneapolis, June 18-20, 1940. The examination covered twelve subjects and included sixty questions. An average of 75 per cent was required to pass. Forty-nine candidates were examined, all of whom passed. Four physicians were licensed by reciprocity to practice medicine and two physicians so licensed by endorsement. The following schools were represented:

Book Notices

Juvenile Delinquents Grown Up. By Sheldon and Eleanor Glueck. Cloth. Price, \$2.50. Pp. 330. New York: Commonwealth Fund; London: Oxford University Press, 1940.

In 1934 the authors of this book published a report covering the careers of 1,000 delinquent boys over a period of five years after they had been brought before a juvenile court. The present work continues the study of as many of the original group as could be found over an additional ten year period. The careers of delinquency or of recovery are described in five year periods, the original work of 1934 constituting the first of these periods. The fifteen years that has elapsed since these boys were before the Boston Juvenile Court, at an average age of 13½ years, have seen them enter adulthood.

The authors note a steady increase in the proportion of delinquents who abandon criminal behavior, and among those who remain delinquent the delinquencies tend to become notably less serious in character. However, a relatively large number of the offenders continue to be delinquent, 226 remaining serious and eighty-eight minor offenders throughout the entire fifteen years of record.

The authors study the factors that correlate with successful and unsuccessful outcomes and make comparisons between reformed and unreformed offenders, serious and minor offenders, and the successes and failures during intramural and extramural treatment. On the basis of differences observed in the comparisons of backgrounds and characteristics of the various groups of offenders, the possibility of predicting with reasonable accuracy the future behavior of the delinquents was explored and prediction tables were constructed based on a few selected factors.

The authors, having demonstrated that with passage of time there is a continuing decrease in the number of youths who continue to be offenders, propose the theory that "the physical and mental changes that comprise the natural process of maturation offer the chief explanation of this improvement in conduct with the passing of the years." Their study reasserts the importance of heredity, "innate equipment" and early environment in favorably influencing the course of delinquency and, presumably, the process of maturation. They are able to distinguish four "conduct types." Type 1 constitutes those who succeeded during some intramural and extramural treatments and are to be distinguished from those of type 2, who failed during both these types of treatment. Members of type 2 are shown to have been subjected to much less favorable circumstances in early life. Inadequate sense of security in early upbringing was reflected in members of type 3, who did well in intramural treatment but poorly in extramural treatment. Members of type 4, who had demonstrated their inability to get along in other group situations in life, failed in institutional treatment but did well in extramural forms of treatment. The authors offer tables predicting behavior during the various forms of penocorrectional treatment on the basis of these differences in treated offenders. It is noted in both intramural and extramural treatment that the behavior of the offenders tended to improve in time, more markedly so during intramural treatment.

The Gluecks recognize two types of "reformed" individuals, those who have achieved a maturity in physical, mental and emotional development that enables them to abandon criminality, and those who abandon criminality as a result of deterioration of their powers. The former are integrated personalities, the latter succumb to the disintegration or deterioration of their faculties.

The authors suggest that their observations, and particularly their prediction tables, could now make possible practical experimentation by courts and parole boards. Disposition of every second case by aid of the prediction tables is proposed, with an eventful follow-up of the two groups thus dealt with. The prediction tables "furnish to courts and parole boards a rational implementation of the indeterminate sentence." The prediction tables also indicate the group of criminals of whom reform or improvement is not to be anticipated.

The Gluecks have done their usual type of thorough job in covering an amazing mass of material, the accumulation of

which in itself called for much resourcefulness. Their observations, their tables and their account of what actually happens to delinquents warrant the closest consideration of all students of criminal behavior. Their studies, as they explicitly state, indicate that there still is much to be learned about delinquency and about the treatment of delinquency. Their emphasis of the role of maturation in delinquency is in agreement, as they indicate, with psychoanalytic formulations of these disturbances in conduct (p. 268). "The next step in developing the theory of the relationship of maturation to delinquency and criminality is to dissect 'maturation' into its components. Such a task must be left to specialists in psychiatry, psychology, physiology, medicine and related disciplines" (p. 270). This suggestion, in effect, brings us back to the precise emphasis in the study to delinquency made by William Healy, Herman Adler and others. It is clear that for prevention of delinquency the specific factors favorably or unfavorably influencing personality growth and development must be understood for the individual delinquent. Alexander and Healy's "Roots of Crime" comes to mind. The Gluecks' suggestions relative to use of their prediction tables may have merit in reducing the guesswork in disposition of delinquents, but there is the problem that prediction tables worked out for the Boston population of delinquents might be of meager usefulness, say, in New Orleans. They properly insist that a better understanding of what actually happens to a delinquent psychologically under various forms of treatment is required. They indicate that further studies contributing to these incompletely understood problems may be undertaken by them. These will be awaited with interest by students of delinquency and criminality.

American Doctors of Destiny: A Collection of Historical Narratives of the Lives of Great American Physicians and Surgeons Whose Service to the Nation and to the World Has Transcended the Scope of Their Profession. By Frank J. Jirka. With an Introduction by Harold W. Camp. Cloth. Price, \$3.75. Pp. 361, with 20 portraits by Raymond Warren. Chicago: Normand House, 1940.

This is a collection of biographic sketches of twenty doctors who, the author believes, are destined for the American Hall of Fame. One should not be too critical of his choice of candidates for this honor, for no two physicians would agree as to who should be selected or even on what basis the selection should be made. But really the group is a motley one. One finds many of the old stand-bys: Benjamin Rush, Ephraim McDowell, Daniel Drake, W. T. G. Morton, Walter Reed and General Gorgas. There are several new ones who are less widely known. The claim for the inclusion of some of these is that they selected, or had thrust upon them, some job—at times a political one—and did the job well. This is, of course, praiseworthy. But, without mentioning names, not all of these are of national caliber. And, as the reviewer looks at it, it shows poor judgment prematurely to include names of men still living and whose life work is far from finished. This is particularly true in the case of those who are apparently so intimately related in a social or medical way to the author as unconsciously perhaps, yet inevitably, to bias his judgment. One questions also the good taste shown by Dr. Jirka in permitting in the introduction extremely laudatory references to himself, with extravagant claims for his accomplishments during his short term of four years in office as director of the Illinois State Department of Public Health. Dr. Harold Camp, who writes this introduction, virtually nominates Dr. Jirka as an American Doctor of Destiny. And Dr. Jirka in a final chapter shows no resentment. The book is a medley of good, bad and mediocre. Some of the best chapters—and there are interesting ones that are well worth reading by the layman—are frankly compiled from biographies written by other hands. There are also many sentiments regarding doctors, their relations to patients and their mission as public servants that are well expressed by Dr. Jirka when writing in his own person and that must be heartily applauded. But there is a too free use of superlatives and too often one finds what sounds more like the ballyhoo of a political speaker than the sober words of an impartial, judicially minded historian or biographer. The drawings by Warren are well done. Several typographic errors have escaped the proofreader. One of these would have made Dr. Oliver Wendell Holmes smile, for it is a reference to his novel as "A Moral Antipathy."

Surgery of the Hand: Some Practical Aspects. By John Harold Couch, M.A., M.B., F.R.C.S., Department of Surgery, University of Toronto and Toronto General Hospital, Toronto. Foreword by W. E. Gallie, M.D., F.R.C.S., Dean of the Faculty of Medicine, University of Toronto. Cloth. Price, \$1.50. Pp. 147, with illustrations. Toronto: University of Toronto Press; London: Oxford University Press, 1939.

The author has compressed a great deal of helpful advice and information into this well illustrated little volume. The repair of injuries of the hand, with particular reference to nerve and tendon injuries, the correct levels for amputation of individual digits, and in part II the important principles involved in the treatment of infections of the hand have been simply and clearly discussed. One point in which we believe the author's advice cannot be taken without question should be mentioned. He says (p. 52) "Movement can be instituted almost immediately after (tendon) suture has been completed, for the strength of the suture will suffice until the tendon is strongly united." The experimental work of Mason and Allen shows that at the end of from eight to fifteen days the newly forming tendon callus is soft and gelatinous; at this stage suture material can be pulled through the callus with but little tension, and movement can result in partial or complete separation at the line of suture. In other words, no form of suture material is proof against separation if mobilization is begun before the tendon callus is firm enough to prevent cutting through of the suture. This volume should prove an invaluable aid to the student and the general practitioner and should help to stimulate the ever increasing interest in this important branch of surgery.

Dynamics of Inflammation: An Inquiry Into the Mechanism of Infectious Processes. By Valy Menkin, Department of Pathology, Harvard University Medical School, Boston. Cloth. Price, \$4.50. Pp. 244, with 50 illustrations. New York: Macmillan Company, 1940.

This volume represents the recent publications of the series of Experimental Biology Monographs designed to give in monographic form the most recent researches in the biologic sciences. The author attempts to describe inflammation from the physiologic, immunologic and biochemical as well as the morphologic point of view, drawing considerably on his own investigations. Inflammation in relation to infectious processes is especially emphasized. Allergic and anaphylactic reactions are discussed with reference to their role in the fixation of antigens. Leukotoxin, a crystalline nitrogenous substance, is offered as the agent responsible for capillary permeability and the migration of leukocytes to points of injury. The context and bibliography should be of value to pathologists and bacteriologists interested in the immunologic and chemical phases of inflammation.

Clinical Heart Disease. By Samuel A. Levine, M.D., F.A.C.P., Assistant Professor of Medicine, Harvard Medical School, Boston. Second edition. Cloth. Price, \$6. Pp. 495, with 109 illustrations. Philadelphia & London: W. B. Saunders Company, 1940.

This is a timely book for the medical student as well as the general practitioner interested in heart disease. The subject matter is presented in simple clear fashion. Throughout, stress is laid and quite properly so on the clinical aspects of heart disease and one is impressed with the author's regard for the patient as an individual as well as the medical problems involved. The personal bedside experiences are interesting and help to emphasize the value of clinical observation and experience.

The new chapter on the medicolegal aspects of heart disease is of current interest and importance and opens up a field which will probably require more consideration in the future on the part of the medical profession. It is highly questionable, however, whether "shadowing" a patient in a medicolegal case is the physician's duty.

Thyroid heart disease with emphasis on "masked thyrocardiacs" is again stressed to help clinicians recognize that group of cases in which such brilliant results are often obtained when the underlying cause of the cardiac disability is recognized and corrected. The author's experience in the treatment of subacute bacterial endocarditis coincides with that of most clinicians. It is suggested that the use of sulfanilamide and heparin in these cases is worth trying. The chapter on acute cardiovascular emergencies should be of value to all practitioners who may be called on at almost any time to administer in such cases. The treatment of congestive heart failure has been enlarged on and

more space is devoted to the subject, which after all is probably the most important part of clinical heart disease for the patient as well as for the doctor. The author's approach to the whole subject is that of the proved and experienced clinician and affords many valuable and practical suggestions for the clinical recognition, evaluation and treatment of the patient with heart failure. A sizable portion of the book is devoted to clinical electrocardiography. The value of the electrocardiogram as well as its limitations is stressed and it is gratifying to have Dr. Levine emphasize the latter and present it in its real place in cardiology. It would seem that too much emphasis and unwarranted importance have been placed on the electrocardiogram by many a present day physician to the exclusion of the more important clinical aspects of heart disease, and this book's views will undoubtedly aid in clarifying the matter. The electrocardiographic illustrations and the text of this particular chapter afford an excellent opportunity to any one interested in learning clinical electrocardiography.

This volume covers the important aspects of heart disease as encountered in practice and has a real place on the list of worthwhile textbooks for the medical student, intern and clinician.

Précis d'oto-rhino-laryngologie. Par Georges Laurens, Maurice Aubry, laryngologiste des hôpitaux de Paris, et André Lemarié, laryngologiste des hôpitaux de Paris. Second edition. Cloth. Price, \$3.90. Pp. 1,241, with 460 illustrations. Paris: Masson & Cie, 1940.

This edition of Laurens's compendium follows the plan that characterizes the entire series of textbooks put out by Masson and Company in presenting a textbook that is not too involved for the student and general practitioner and yet is ample as a reference book for the young laryngologist. The new items added since the first edition comprise chapters on audiometry, petrositis, cancer of the hypopharynx, pharyngeal manifestations of hematologic conditions, dyspnea in infants and radiography in cancer of the larynx, which bring the text down to date. The author and his associates have carefully adhered to known and accepted facts and principles, avoiding items that are more or less controversial. An index of their restraint for example is manifest in their conservative discussion of retrobulbar neuritis in relation to posterior sinus disease, a topic on which many of the French authors are particularly radical. The book covers the vast territory in necessarily concise style and almost everything in the domain of otolaryngology receives some mention. While the illustrations are not particularly artistic, they serve the purpose. It is interesting to note that at the time the book was issued its cost in American money was only \$3.90, which is remarkably cheap for a textbook of its size and character. For those who have a reading knowledge of the French language it is both interesting and stimulating to peruse this book and to note that though it differs from our own textbooks in some minor details it compares favorably with some of our best.

Artificial Limbs and Their Relation to Amputations. Ministry of Pensions. Cloth. Price, 90 cents; 3s 4d. Pp. 88, with 42 illustrations. New York: British Library of Information; London: His Majesty's Stationery Office, 1939.

The large number of casualties in the war of 1914-1918 provided an important proving ground for the development of artificial limbs. This experience was utilized by the British Ministry of Pensions to develop acceptable standards of appliances to meet the needs of amputees. The result of this work has been crystallized into the present small volume, which briefly yet completely describes ideal sites and methods of amputation, types of artificial limbs and appliances, and methods of fitting. The publication is particularly timely because of the present war and provides a basis for the management of similar problems that are sure to arise among the new amputees. The reviewer's experience has been confined for the most part to the problems of civilian amputees, but their problems and those of the war disabled are not dissimilar. However, the use of temporary prostheses such as plaster pylons has not been considered necessary in this country, since thigh lacers and other methods of preliminary shrinking have been generally considered adequate. While the book should be of value to military, industrial and orthopedic surgeons, it is of especial importance to administrative agencies which may be concerned with the problems of organization in the field of rehabilitation of the amputation cases.

Manuel de classification et de détermination des bactéries anaérobies. Par André R. Prévot, chef de service—adjoint à l'Institut Pasteur. Paper. Price, \$1.15. Pp. 223, with one illustration. Paris: Masson & Cie, 1940.

The author states in the preface that he has had seventeen years of experience in working with anaerobes. He has been interested in the classification of anaerobes and is a member of the International Committee on the Classification of Bacteria. The purpose of this manual is to afford a working classification of the anaerobes. The author was urged by his friends in the army to get out rapidly a book which would be helpful to the laboratory staff in classifying anaerobes from various wound infections. This book was put out in response to that demand. The author believes that the three most important features in classifying anaerobes are spore formation, Gram stain and motility. He, of course, takes into account morphology, general physiology, cultural and biochemical reactions, pathogenicity and serologic and immunologic reactions. The book is comprehensive and catalogues the nonsporulating as well as the sporulating anaerobes, cocci, actinomycetes and spirochetes. Many new families and genera have been added. For instance, *Bacillus tetani* or *Clostridium tetani* is listed in the order of Plectridiales, the family Plectridiaceae and the genus Plectridium and is called Plectridium tetani. *Bacillus welchii* or *Clostridium welchii* is in the family Clostridiaceae and in the genus Welchia and is called Welchia perfringens. The creation of new names for the anaerobes is going to add to the long list of names which some of them now have. The anaerobes have been much neglected by medical bacteriologists and this book should prove stimulating to physicians as well as to laboratory workers.

For Daughters and Mothers. By Valeria Hopkins Parker, M.D., Director, Bureau of Marriage Council and Education for Social and Family Relations. Cloth. Price, \$1.50. Pp. 138. Indianapolis & New York: Bobbs-Merrill Company, 1940.

This is a book on relationships between mothers and daughters as daughters enter adolescence. It deals largely with sex development in adolescence but also gives considerable attention to other problems, particularly the growth of independence and impatience at restraint which characterize the adolescent. The book contains much excellent advice, both for mothers and for daughters, about how to live harmoniously in spite of frequently clashing points of view due to difference in age and outlook. The chapter headings are descriptive of the content of the book, dealing as they do with childhood, new horizons and new outlooks, the chain of life, new bodies, "having a good time," looking toward romance, "how do you know when you're in love?", working plans, women of tomorrow, and the great adventure. Toward the end of the book the chapters begin to be a trifle sketchy and to give the impression of having been prepared less thoroughly than the earlier chapters. In general, however, the book can be recommended to physicians who seek books of this type to recommend to their patients.

Lectures on Motor Anomalies. By Alfred Bielschowsky, M.D. Foreword by Walter B. Lancaster, M.D. Paper. Price, \$1. Pp. 128, with 62 illustrations. Hanover, New Hampshire: Dartmouth College Publications, 1940.

The twelve lectures of this monograph were delivered before the Research Study Club of Los Angeles in January 1938. They were first published in the *American Journal of Ophthalmology* in a series beginning in August 1938 and ending in August 1939. Coming from the University of Breslau in Silesia in 1934, the author gave more than a hundred lectures and demonstrations on ocular motility. Remaining in the United States as head of the Eye Clinic of Dartmouth College, Dr. Bielschowsky died suddenly in New York January 5 and was deprived of the opportunity to realize his cherished plan of writing a comprehensive textbook in English on the special field in which he attained world renown. In the foreword by Dr. Lancaster the final statement that "the lectures which are collected in this volume are a small but vivid token of his knowledge, experience and didactic ability" is indeed true. Those of us who enjoyed the privilege of hearing Dr. Bielschowsky lecture were intrigued by his simple, understandable delivery, which is reflected in this work. Controversial subjects are approached from all angles, due credit is given to various authorities with dignified humility, and the whys and wherefores of the author's own views are simply told. The author's vast experience in this limited field

and his knowledge of the fundamental physiology and pathology of the ocular muscles, together with his neurologic acumen reflected in these lectures, makes for the inclusion of this volume in the library of every ophthalmologist.

The Varieties of Human Physique: An Introduction to Constitutional Psychology. By W. H. Sheldon, Ph.D., M.D. With the collaboration of S. S. Stevens, Ph.D., and W. B. Tucker. Cloth. Price, \$4.50. Pp. 347, with 104 illustrations. New York & London: Harper & Brothers, 1940.

The authors point out the need for a description of human physiques which can readily be obtained and which can be of use in studies of personality and clinical problems. They outline a method for "somatotyping" an individual. It consists of photographing an individual from the front, side and back and then evaluating the figures on the negative or print. The evaluation is in part anthroposcopic and in part anthropometric. A number consisting of three digits is finally obtained. Each digit may range from 1 to 7. For example, 154 and 714 are typical evaluations. The authors claim a high degree of reliability for their evaluations. The book is easily read but unnecessarily long. Its usefulness would have been increased had it been concise. What value "somatotyping" may serve is problematic. There is without doubt a need for physical measurements on a large scale which can be used for correlation with other physical and mental characteristics, but it is questionable whether somatotyping will serve that need. Perhaps it will for a time.

St. Thomas's Hospital Reports. Edited by Prof. O. L. V. S. de Wesselow and Mr. C. Max Page. Assisted by Mr. N. R. Barrett, Dr. J. St. C. Elkington and Dr. A. J. Wrigley. Second Series. Vol. IV. Cloth. Price, 10s. Pp. 198, with illustrations. London, 1939.

Here are collected a group of papers by members of the St. Thomas staff. Some papers, such as these on oxygen therapy, cerebral abscess, empyema and orbital inflammation, are instructional and deal with technics and clinical observations and indications. A review of the male sex hormone is followed by a case report of macrogenitosomia in one of twin boys. The surgical treatment of gastroduodenal hemorrhage is discussed. The anatomic changes associated with closure of the ductus arteriosus are outlined in pathologic changes in the wall of the ductus arteriosus. Other titles include acetylcholine and potassium in relation to cardiac function, thorium-x irradiation in cutaneous therapy and estimation of the water soluble vitamins in the body fluid. The typography is excellent.

An Index of Treatment. By Various Writers. Edited by Sir Robert Hutchison, Bt., M.D., LL.D., Consulting Physician, London Hospital, London. Assisted by Reginald Hilton, M.A., M.D., F.R.C.P., Physician to St. Thomas's Hospital, London. Twelfth edition. Cloth. Price, \$12. Pp. 996, with 148 illustrations. Baltimore: William Wood & Company, 1940.

In the present edition of this companion volume to the equally well known index of differential diagnosis, of which French is editor, no alterations in plan or format have been made. The number of individual contributors has been reduced from ninety-one to seventy-eight. A few subjects make their appearance for the first time, the principal ones being bone setting, rat bite fever, sebaceous cysts and syndactyly. Few of the treatises seem to have been completely rewritten—an unfortunate fact in certain instances, notably pneumonia. The book must continue to disappoint those who wish to have an unprejudiced and inclusive therapy presented in a specific fashion.

Die geburtshilflichen Operationen: Ihre Ausführung und Anwendung. Ein Lehrbuch für Studierende und Gebrauchsbuch für Ärzte. Von Prof. Dr. med. Heinrich Marthus, Direktor der Universitäts-Frauenklinik Göttingen. Second edition. Paper. Price, 12 marks. Pp. 286, with 281 illustrations. Leipzig: Georg Thieme, 1940.

This book is devoted almost entirely to obstetric operations including perineal lacerations, forceps operations, breech extraction, version and extraction, manual removal of the placenta and cesarean section. At the beginning are large sections on the obstetric pelvis and the mechanism of labor. The illustrations, nearly all of which have been beautifully drawn, are the chief asset of the book. This is as it should be, because any book dealing with operative procedures should have numerous instructive illustrations. There is nothing new in the book, because its entire contents may be found in any of the standard textbooks of obstetrics. Hence the need of such a book is questionable.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Harrison Narcotic Act: "Prescribing" Narcotics for Addicts.—Defendant Heller, a physician, was prosecuted for violation of the Harrison Narcotic Act on a charge that he had entered into a conspiracy with defendant Kuhn, a pharmacist, to supply narcotic drugs to narcotic addicts, not for the treatment of bona fide patients but to satisfy the craving of addicts for their drug of addiction. The physician wrote fraudulent prescriptions which the pharmacist filled. The evidence showed that sometimes the physician left the prescriptions undated so that they might be dated by the pharmacist in such a way as to present a record that would not excite the suspicion of the narcotic inspectors. A witness for the government, a narcotic addict who claimed to be suffering from myocarditis and amebic dysentery but was able to carry on his usual occupation, testified that on week ends he traveled from his home to defendant Heller's office and returned, a distance of 180 miles each way, in order to secure prescriptions for morphine which he had filled by the co-defendant pharmacist. Forty-three prescriptions, signed by Dr. Heller, which purported to have been issued for "incurable chronic angina and chronic amebic dysentery" were introduced in evidence. An expert medical witness for the government testified that a patient suffering from myocarditis whose condition justifies the use of morphine should be at absolute rest in bed. In answer to a hypothetical question, this expert witness further testified that the use of morphine was not justified in the case of a person suffering from myocarditis whose condition was such that he was able to carry on his usual occupation and travel 360 miles each week end. In his opinion morphine is used in cases of myocarditis to relax the patient and to take as much load off the heart as possible, but for this purpose the use of a drachm (4 Gm.) every six or seven days would be indicated only in a "rather rare case." On this evidence the defendants were convicted of a conspiracy to violate the Harrison Narcotic Act. The pharmacist was admitted to probation, but the physician was sentenced to prison and so he appealed to the United States circuit court of appeals, fourth circuit.

Defendant Heller's contention, that the government's expert medical witness had not taken into account the fact that the patient was a morphine addict when he expressed his opinion as to how much morphine was proper in the treatment of myocarditis, did not meet with the approval of the circuit court of appeals. The mere fact, said the court, that a patient supposed to be suffering from myocarditis was making trips of 360 miles each week end to secure a prescription for morphine spoke so loudly as to the real situation existing that any testimony as to proper dosage for such an ailment would hardly be noticed. The court concluded that the conviction of violation of the Harrison Narcotic Act was amply sustained by the evidence. Accordingly, the judgment of conviction was affirmed.—*Heller v. United States*, 104 F. (2d) 446.

Medical Practice Act (Florida): Constitutionality; Revocation by Board on Criminal Charge Not Barred by Court Acquittal.—De Gaetani, a physician, was prosecuted and acquitted in a criminal court on a charge of criminal abortion. Subsequently the Florida state board of medical examiners, pursuant to authority granted by the medical practice act of Florida and after a hearing in a county other than that in which the alleged criminal offense occurred, revoked the physician's license to practice medicine. From an order of the circuit court, Dade County, denying the petition of the state, on the relation of the physician, for a writ of certiorari to review the action of the board, and in effect ordering a trial de novo, the relator appealed to the Supreme Court of Florida.

The appellant physician contended that his acquittal by a criminal court of the charge of criminal abortion was an absolute bar to any proceeding by the state board of medical exam-

iners to revoke his license. The Supreme Court conceded that there is a division of authority on this question but believed the better reasoned rule to be, as it had recently announced in *State ex rel. Sbordy v. Rowlett* (Fla.), 190 So. 59, that an acquittal in a criminal prosecution will not bar a proceeding by the board to revoke a physician's license based on the same offense. It was not necessary that the hearing of the board be held, as the appellant argued, in the county where the cause of action accrued. In the judgment of the court, the medical practice act was not unconstitutional because it does not in terms provide a means for summoning and enforcing attendance of witnesses. In refutation of the appellant's further contention that the act was unconstitutional because in the trial de novo it does not accord the accused a jury trial, the court pointed out that the appellant had not requested such a trial and, furthermore, the proceeding before the board was not a criminal prosecution and was not therefore an action in which the appellant was constitutionally entitled to a trial by jury. The judgment of the lower court was therefore affirmed.—*State ex rel. De Gaetani v. Driskell et al., State Board of Medical Examiners (Fla.)*, 190 So. 461.

Governmental Hospitals: Liability for Failure of Hospital Attendants Properly to Supervise Inmates.—In two cases the court of claims of New York held that the state was liable in damages for the negligence of attendants at a state psychiatric hospital in failing properly to supervise inmates of the institution. In one case the patient was gored to death by a bull and in the other case the inmate hung himself. Both patients were suffering from dementia praecox and in each case the attendant knew of the inmate's low mentality and suicidal tendencies. In the opinion of the court in each case the amount of damages recoverable was dependent on the pecuniary loss actually sustained by the surviving widow or children. But, in view of the fact that in each case the medical testimony showed that the patient had been suffering from an incurable disease and would never have been able to contribute financial assistance to his family had he lived, the court held that the surviving heirs had sustained no pecuniary loss other than the cost of burial. Accordingly, the court in each case limited recovery to the amount of reasonable funeral expenses.—*Dimitroff v. State (N. Y.)*, 13 N. Y. S. (2d) 458; *Gaccione v. State (N. Y.)*, 18 N. Y. S. (2d) 161.

COMING MEETINGS

- American Academy of Pediatrics, Memphis, Tenn., Nov. 18-20. Dr. Clifford G. Grulee, 636 Church Street, Evanston, Ill., Secretary.
- American Clinical and Climatological Association, White Sulphur Springs, W. Va., Oct. 28-30. Dr. Francis M. Rackemann, 263 Beacon St., Boston, Secretary.
- American College of Surgeons, Chicago, Oct. 21-25. Dr. Frederic A. Besley, 40 East Erie St., Chicago, Secretary.
- American Society of Tropical Medicine, Louisville, Ky., Nov. 12-15. Dr. E. Harold Hinman, Malaria Control Division, Wilson Dam, Ala., Secretary.
- Central Society for Clinical Research, Chicago, Nov. 1-2. Dr. Carl V. Moore, Washington University School of Medicine, St. Louis, Secretary.
- Clinical Orthopaedic Society, Milwaukee and Madison, Wis., Oct. 18-19. Dr. Myron O. Henry, 825 Nicollet Ave., Minneapolis, Secretary.
- District of Columbia, Medical Society of the, Washington, Oct. 15-17. Mr. Theodore Wiprud, 1718 M St., N.W., Washington, Secretary.
- Indiana State Medical Association, French Lick, Oct. 29-31. Mr. Thomas A. Hendricks, 23 East Ohio St., Indianapolis, Executive Secretary.
- Inter-State Postgraduate Medical Association of North America, Cleveland, Oct. 14-18. Dr. W. B. Peck, 27 East Stephenson St., Freeport, Ill., Managing Director.
- New York State Association of Public Health Laboratories, Albany, Nov. 1. Miss Mary B. Kirkbride, New Scotland Avenue, Albany, Secretary.
- Omaha Mid-West Clinical Society, Omaha, Oct. 28-Nov. 1. Dr. J. D. McCarthy, 107 South 17th St., Omaha, Secretary.
- Pacific Coast Society of Obstetrics and Gynecology, San Francisco, Nov. 6-9. Dr. T. Floyd Bell, 400 Twenty-Ninth St., Oakland, Calif., Secretary.
- Radiological Society of North America, Cleveland, Dec. 2-6. Dr. Donald S. Childs, 607 Medical Arts Bldg., Syracuse, N. Y., Secretary.
- Southern Medical Association, Louisville, Ky., Nov. 12-15. Mr. C. P. Loranz, Empire Bldg., Birmingham, Ala., Secretary.
- Southwestern Medical Association, Tucson, Ariz., Nov. 21-23. Dr. M. P. Spearman, 1001 First National Bank Bldg., El Paso, Texas, Secretary.
- Western Surgical Association, Topeka, Kan., Dec. 6-7. Dr. Albert H. Montgomery, 122 South Michigan Blvd., Chicago, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to members of the Association and to individual subscribers in continental United States and Canada for a period of three days. Three journals may be borrowed at a time. Periodicals are available from 1930 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

- Dissecting Aneurysm: Report of Nineteen Cases, with Review of Recent American Literature. L. F. Holland, Austin, Texas, and R. H. Bayley, New Orleans.—p. 223.

Prodromal Pain in Coronary Occlusion.—Blumenthal and Reisinger discuss the prodromal pain that occurred spontaneously, without obvious cause, and always preceded definite manifestations of coronary occlusion. Histories of thirty-two patients revealed that twelve had experienced such attacks for varying periods before the severe manifestations recognized as coronary occlusion occurred. Nine of the thirty-two patients died, one of whom was in the "prodromal" group. The mechanism of the production of the "prodromal" pain in this case is discussed in the light of pathologic anatomy. The duration, character and length of the prodromal period of pain varied from patient to patient. Generally the attack appeared suddenly, without obvious precipitating causes, when the patient was apparently in good health. The pain usually developed while the patient was at rest. The attacks of five patients were associated with exertion, but in these instances the pain either was not relieved by cessation of the exercise or began after the exercise was stopped. Nine patients were able to do fairly strenuous work without discomfort on the same day on which they had spontaneous attacks of pain. One patient had attacks of angina of effort which were relieved promptly by rest, but he also had other pain which he himself differentiated from angina of effort, which was not associated with exercise, emotional excitement or eating. The pain varied in duration from fifteen minutes to hours and from a mild ache to extreme severity. It was variously described as burning, gnawing, constricting, toothache-like, gripping, aching, swelling, and crushing. The character of the pain remained constant during the prodromal period, but its severity, duration and area involved increased with succeeding attacks. Usually the pain was referred to the anterior chest wall between the midclavicular lines. Ultimately it was always located in this area. The pain of three patients did not involve the chest primarily; severe aching and weakness of the left arm, intermittent pain in both shoulders for a week before the coronary occlusion and pain in the left elbow for six days preceded the onset of pain in the chest. One patient had had pain in the left shoulder for three years. Pain and extreme weakness in one or both upper extremities associated with the premonitory manifestations were noticed by six patients. Subsequent events indicated that the peripheral pain and weakness were related to the changes in the heart and coronary arteries. Between prodromal attacks the patients felt well, except for transient

weakness. Four patients were examined between attacks and no signs of myocardial infarction were found. Electrocardiograms of three patients showed no changes typical of coronary occlusion. The authors discuss the mechanisms that may be responsible for prodromal pain. They believe that of the many factors which contribute to it intramural hemorrhage may be an important one.

Roentgenography and Duodenal Drainage in Cholelithiasis.—Levyn and Meyers compared the relative value of x-rays and examination of the duodenal contents in the diagnosis of cholelithiasis in fifty-four cases. The diagnoses were verified by surgical exploration and pathologic examination. Some of the patients were suffering from other diseases, such as hepatic or gastric carcinoma, peptic ulcer, pancreatitis and postoperative adhesions. Cholecystographic examinations were conducted by the oral method, tetraiodophenolphthalein being administered in 4 Gm. doses. Duodenal drainage was performed according to the method of Lyon. The bile obtained from the duodenum was examined microscopically after being centrifuged for pigment and crystals, the presence of which is indicative of stones in the gallbladder and biliary ducts, and for the amount of B bile present. When from 30 to 50 cc. of B bile was obtained the function of the gallbladder was considered normal and conclusions were drawn as to the presence or absence of stones in the gallbladder. When B bile is absent or only a slight trace is recovered after repeated drainage it may be impossible to determine the presence or absence of gallstones. Occasionally pigment and crystals may be found

in the absence of B bile. This is considered indicative of intraductal stones or biliary stasis. The finding of cholesterol crystals or calcium bilirubinate pigment, or both, in the same sediment was considered as evidence of calculi in the biliary tract. The fifty-four cases were divided into two groups: the thirty-three in which gallstones were found and the twenty-one in which gallstones were not found at operation or necropsy. In those cases in which gallstones were found, a positive diagnosis was made roentgenographically by actual demonstration of their shadows in fifteen. Suggestive, but not positive, evidence was observed in three additional cases. The primary films made the positive diagnosis of cholelithiasis in the majority of cases, and cholecystography helped to establish definite evidence of shadows in only three cases, when they were absent on the primary films. The diagnosis of calculi by means of duodenal drainage was positive in twenty-eight of the thirty-three cases. Therefore the positive identification of stone shadows, when present, was accomplished by x-ray examination in 45.5 per cent, while duodenal drainage gave such evidence in 85 per cent. Both methods gave no positive evidence of calculi in three of the thirty-three cases. In no instance of the other group of cases did cholecystography reveal stone shadows, while duodenal drainage indicated gallstones in seven cases when they were not present. The presence of pigment and crystals in individuals without gallstones has been previously reported by Bockus and his co-workers. In five cases, after surgical exploration of the biliary tract and microscopic study of the wall of the gallbladder there was no accountable reason for the presence of pigment and crystals in the duodenal contents. In one the precipitation of pigment could have been explained by the fact that the patient was deeply jaundiced and in another by severe cholecystic disease without stones.

Deleterious Pulmonary Effects of High Voltage Roentgen Irradiation.—Jacobsen records a postmortem study of the case of a man with a clinical diagnosis of cancer of the lung who was subjected to high voltage roentgen therapy over a period of nine years and whose death was undoubtedly the result of the therapy and not of the neoplasm. During the nine years about 15,800 roentgens was given to the right chest. X-ray evidence during this long interval was compatible with cancer of the right lung. There was no significant loss of weight and little evidence of anemia. Frequent roentgenograms showed slowly progressive fibrosis of the right lung, thickening of the pleura, marked elevation and fixation of the diaphragm, narrowing of the intercostal spaces and retraction of the mediastinal structures to the affected side. This syndrome, following prolonged high voltage irradiation, is almost pathognomonic of roentgen pleuropulmonitis. The conversion of lung into scar tissue increased the vascularity of the bronchial lining. This led to frequent hemoptysis, often of alarming proportions. Irradiation aided in stopping these hemorrhages and was often used for this purpose. Thus a vicious circle was established. Death occurred from an acute influenza-like pneumonia sixteen years after his first symptoms, with secondary septicemia and kidney abscesses. Necropsy revealed the right lung to be converted into a structure of fibrous consistency the size of a man's fist. The pleura was about 4 mm. thick and of almost cartilaginous hardness. Atelectasis was present wherever there was enough lung structure for this to occur. Embedded in a dense mass of fibrous tissue just outside the hilus was an epithelial tumor 2 cm. in diameter with a necrotic center and a viable periphery. The diagnosis was therefore correct and the treatment was successful in that it destroyed most of the tumor and held the small remnant in subjection. Just how much of the vascular pulmonary damage was due directly to roentgen irradiation is open to conjecture. The cellular structure of the lung places it in the group of less radiosensitive organs. With the high voltages and deep penetrability of modern x-ray equipment, destruction or inhibition of tumors in the chest is being accomplished, but at the same time changes in the non-tumor containing portions of the irradiated lung are being detected. Generally these are of minor clinical import but many reports are accumulating which indicate a danger which must be appreciated and guarded against. The widespread alteration in pulmonary tissue, of a

kind that greatly decreases pulmonary volume, doubles the work of the opposite lung and increases the chances of infection. An increase in such complications is prophesied unless improvements in radiation technic are forthcoming. Before a roentgenologist gives additional roentgen therapy to a patient, it is mandatory that he be in possession of facts concerning all previous exposures. Neglect in obtaining such information may in the future lay the physician open to the charge of lack of due care.

Pleural Effusion in Pneumothorax.—Eng states that of 394 consecutive pneumothorax cases 269, or 68.3 per cent, formed fluid which remained a week or more. This was observed on fluoroscopic examinations performed at intervals of from three to fourteen days. The fluid formed within the first three months in 50.5 per cent, within six months in 67.1 per cent and within a year in 85.6 per cent. The incidence of fluid was greatest in far advanced cases, less in the moderately advanced and least in the minimal. Therefore a great number of effusion cases can be safely avoided by establishing pneumothorax in early lesions. Of the forty-nine deaths in the cases under consideration, fluid developed in forty and only two of these did not show far advanced lesions. Empyema developed in forty-nine of the 134 cases in which aspiration was done. The empyemas of twenty-one cases were aspirated and irrigated with physiologic solution of sodium chloride until the fluid withdrawn was clear and then from 10 to 50 cc. of azochloramid 1:3,300 or the same amount of azochloramid in triacetin 1:500 was injected. Aspirations were done at weekly intervals. The twenty-one patients tolerated the former solution well, having no reaction most of the time or but a mild degree of pain and fever for from a few hours to one day following the injection, whereas the four patients given the latter solution had either a marked elevation of temperature or considerable pain and showed no improvement after six or more treatments. With the 1:3,300 solution the pus gradually became thinner, less in quantity and finally either disappeared entirely or was replaced by a small amount of clear straw colored fluid in eighteen cases. Constitutional improvement occurred, the toxic symptoms of empyema disappeared and appetite and weight increased gradually.

Tuberculin Tests and Roentgenograms.—Crimm and his colleagues state that 1,000 adults of native stock from 16 to 70 years of age were divided into two groups and given intracutaneous tuberculin purified protein derivative tests. Roentgenograms were made of reactors and nonreactors alike. The first group of 553 individuals were given 0.00002 mg. of purified protein derivative intracutaneously; 429 of the 553 were negative to this dose at forty-eight hours and were then given 0.001 mg. of purified protein derivative. The second group of 447 individuals were tested simultaneously in one arm with

0.00002 mg. of purified protein derivative and in the other with 0.001 mg. The incidence of contact cases was 13.6 per cent; 76.7 per cent of all the cases showed evidence of previous tuberculous infection either by the tuberculin test and/or by the roentgenogram. Two active cases were found in the entire series. Of the total cases showing evidence of tuberculosis, 72.1 per cent were found by the tuberculin test and 69.9 per cent through x-ray study. If only the tuberculin test had been employed the incidence of infection would have been 55.3 per cent, and if the x-ray examination had been the only procedure it would have been 53.5 per cent. However, since only two active cases were found, the experiment shows that mass examination by the tuberculin test and x-ray study of the adult is quite expensive in this locality. One of the active cases could have been found through adequate follow-up work because of a history of contact. The other person consulted a physician two weeks prior to the test and would ultimately have been admitted to a sanatorium. Therefore this method of case finding is too expensive for the results it gave. As follow-up work on discharged patients from sanatoriums, the recording of all patients and contacts with state boards of health, the isolation and quarantine of open cases by health officials and earlier diagnosis on the part of the medical profession, together with education of the public, are necessary in a complete case-finding program, the authors believe that efforts should be centered on these projects rather than on mass x-ray examination and mass tuberculin testing. Tuberculin testing of special groups is valuable as an educational program, even though its case-finding efficiency is limited.

Spontaneous Cerebral Ventriculostium.—Sweet reports two instances of spontaneous development of an opening between the third ventricle or the lateral ventricles and the external surface of the brain. Such openings develop as a consequence of expansion of the cerebral ventricles when the flow of cerebrospinal fluid is obstructed. In the only other case reported in the literature the obstruction took place at the aqueduct of Sylvius. In the author's second case the block was at the same site, and in his first case the obstruction was due to an enormous teratoid tumor in the posterior cranial fossa. The first patient, a woman of 54, was admitted to the hospital in an extremely confused mental state. She dated all her symptoms to two days previously. A history of symptoms beginning twelve years previously was obtained from her family and her physician. A diagnosis of probable right cerebral glioma was made and the patient was discharged. Within a few weeks the defects in her memory and gait had practically disappeared and she was apparently well for nine years, when she was found unconscious on the sidewalk. Despite the unusual history, the marked cerebellar signs and calcification strongly suggested a neoplasm, but pneumo-encephalographic examination or suboccipital exploration was not carried out

because of the patient's poor general condition. She also presented hypertension, bronchopneumonia and pyuria; acute pulmonary edema and hyperpyrexia developed four days after entry, and the patient died the next day. Necropsy revealed a midline cerebellar teratoid tumor with moderate secondary hydrocephalus and rupture through the lamina terminalis. The author believes that the complete subsidence of symptoms for nine years is probably to be correlated with the abnormal opening in the lamina terminalis. It was unlikely that this was an artefact. The possibility that the subsidence of the symptoms was due to spontaneous rupture of the cystic tumor is not tenable, as there was no evidence of cystic contents in the subarachnoid space. Also the tumor was multilocular, and it is unlikely that enough locules would have broken simultaneously to cause all symptoms to disappear. The author believes that the nine years of freedom from symptoms was due to the spontaneous development of a third ventriculostium. This favors the similar operative procedure recommended by Dandy and by Stookey and Scarff for relief of hydrocephalus from occlusion of the aqueduct of Sylvius. The ventriculostium continued patent and functioning for nine years and was apparently still effective at the time of death. In the other case, in a boy of 15, in which there was a spontaneous ventriculostium, the hydrocephalus was not relieved as no communication was established with the subarachnoid space. Because of marked involvement of the posterior cranial nerves and cerebellar seizures and signs, the clinical diagnosis was between a cerebellar and a metencephalic tumor. Postmortem study was restricted to the brain, and the primary source was found to be a tumor of the brain stem. A conspicuous nodule of it lay in the midline of the tectum of the midbrain, between the superior colliculi and occluding the rostral portion of the aqueduct of Sylvius. The signs of involvement of the structures in the posterior fossa were due not only to their invasion by the tumor but to the fact that they were not given the usual protection by the tentorium cerebelli; there was in effect a large fluid tumor in the upper part of the posterior fossa. The widely dilated pupils which gave no reaction to direct light constituted the only sign of destruction of tissue in the tectum mesencephali by the tumor. The boy's obesity and retardation of sexual maturity were ascribed to secondary pressure on the hypothalamus and pituitary gland with the resultant atrophy. The extensive destruction of nerve tissue precluded any attempt to localize the site of origin of terminal cardiovascular attacks.

Comparison of Metrazol and Control Treatment of Schizophrenia.—Notkin and his co-workers present the results obtained in schizophrenic patients treated with metrazol and those given injections of physiologic solution of sodium chloride. The control patients were kept in bed in the same ward with the patients treated with metrazol. The study is based on the treatment of fifty men and fifty women with metrazol, thirty-four men and thirty-seven women controls and twelve men and three women who recovered or improved while awaiting treatment. The duration of the psychosis was more than eighteen months in 78 per cent of patients in the treated group, in 84.5 per cent of the control group and in only 13.4 per cent of the patients who improved spontaneously. The patients were followed for from six months to one and a half years after the termination of treatment or control observation. Of the 100 treated patients, 18 per cent showed various degrees of improvement. One man died of an abscess of the lung which developed after the thirteenth convulsion. The remaining eighty-one patients failed to show any change in their mental condition. Of the patients who improved, seventeen were released and two have had relapses and were returned to the hospital. Of the seventy-one control patients, six (8.4 per cent) showed various degrees of improvement and sixty-five failed to improve. Five of these improved patients were discharged and two have had relapses and have been returned to the hospital. Of the fifteen patients who improved spontaneously, one had a relapse while still in the hospital and two others have had relapses after their release. None of the treated or the control patients recovered. Recoveries occurred in 14.3 per cent of the patients showing spontaneous improvement. Patients with a shorter duration of the psychosis had

longer remissions. The patients in both groups who improved were younger than the patients who did not improve. The convulsive threshold was lower in women. The paranoid and the catatonic types of psychoses were equally represented in the improved treated patients, while in the control group the catatonic type predominated. The paranoid type predominated in both groups of unimproved patients, as it did in the group who improved spontaneously. All patients who improved showed a gain in weight. From one to seven temporomandibular dislocations during convulsions were encountered among fourteen patients. An incomplete fracture of the femur and a dislocation of the humerus occurred in two other patients. A transitory rise of blood pressure and an increase in pulse rate followed all convulsions.

Factors Causing Prothrombin Deficiencies.—Andrus and Lord studied the plasma prothrombin levels in two groups of cases with disorders of the biliary tract and other conditions associated with deficiencies in the clotting component. In the first series twenty-two patients were found to have low prothrombin levels and were treated with vitamin K (klotogen or cerophyl) and bile salts (bilon). With this therapy and transfusions for some of the patients, hemorrhage ceased when it was present at admission or its subsequent occurrence was prevented except in one patient who died. This patient had a carcinoma involving the bile passages and died from a massive hemorrhage from an ulcer on the posterior aspect of the duodenum which had eroded into the pancreaticoduodenal artery. This patient's prothrombin level had previously been low but had responded to treatment and at the time of the hemorrhage was normal. Quite obviously the bleeding was unconnected with any prothrombin deficiency. Since October 1939 the authors have used the synthetic vitamin K, 2-methyl-1, 4-naphthoquinone, intramuscularly for thirty-eight cases with prothrombin deficiencies, with strikingly successful results in the absence of damage to the liver. When it is given by injection, the presence of bile salts in the intestinal tract is not necessary for its absorption, and its effect is evident within a few hours. The clinical effectiveness of vitamin K may be diminished or even abolished in the presence of severe hepatic damage. Two cases are cited to illustrate the influence of hepatic damage on the level of plasma prothrombin and on the response to vitamin K. One was a case of thrombosis of the hepatic artery and the other of marked cirrhosis. Vitamin K medication had no effect here on the prothrombin level.

Metaplasia of Breast.—Comprehensive review of the literature, according to Oliver, revealed no reference to pavement epithelium of primary origin in the mammary gland. He reports three such cases and reviews the physiology of the breast and abnormalities associated with faulty cyclic processes described by Oliver and Major as cyclomastopathy. The pavement type of epithelium in the three cases was deeply embedded in growths of cyclomastopathic origin and could not have been the result of the growing over of surface epithelium, which must be ruled out in all cases of suspected metaplastic processes. The presence of pavement epithelium in such a growth bears out the contention that mechanical stimuli may aid in inaugurating metaplastic processes. Whether embryonal displacement, simple retrogression or direct metaplasia is responsible for the change is a theoretical question. The fact that the change has taken place and is associated with changes similar to metaplasia must be considered. The variation from the glandular to the pavement type of cell indicates that the process is an indirect one, transitional changes being necessary for the transformation, as against the direct process, in which a specialized cell or tissue is changed into another specific cell or tissue without intermediate stages. Such an abrupt change was not seen in any of the sections. The author's views on the possible mechanisms by which metaplasia and its associated processes may be brought about are: 1. In consideration of the derivation of metaplastic processes from a germinal cell or tissue, certain cells of the original germinal stock from which the specialized cell or tissue is derived may remain undifferentiated, though in their development they are carried along with the differentiated cells. 2. In the growth of cells or a tissue toward a certain specialization, there is a possibility that some cells may be retarded in their differentiation and may remain so, as do the completely undifferentiated cells in the specialized tissue. These cells may also develop along lines foreign to the site and thus appear different from those of the tissue considered. 3. The transformation of one specialized cell or tissue into another different specialized cell or tissue is doubtful and rarely, if ever, occurs in a direct manner, although the possibility must be considered.

Fuchs Test for Cancer.—Robinson and his associates employed the Fuchs test in 200 cases for the diagnosis of malignant conditions. They obtained seventy-four negative reactions in cases in which evidence of a malignant process was not to be found. The presence of a malignant tumor was suspected among ten but the growth was proved on biopsy to be benign. There were a number of negative values corresponding to Fuchs's "immune reaction," most of which were too small to be significant. In fifty-six cases of proved malignant tumor the Fuchs reaction was positive. The interest of the test lies in the wide variety of tumors which give positive reactions. The test gave negative reactions in some patients who either had or had previously had proved malignant tumors. The majority of these patients had undergone some therapy, after which the tumor showed no signs of recurrence. If it is assumed that the Fuchs reaction would have been positive prior to treatment, the effects of therapy are rather prompt. In one instance (sarcoma of the jaw) a negative reaction was obtained as soon as six days after operation, while in another case (squamous carcinoma of cervix) it was not negative until eight months after operation and high voltage roentgen therapy. At the time the test was negative and one week later this patient was much improved. That the test measures the activity of the malignant growth is indicated by a case of carcinoma of the breast. On admission the patient was found to have extensive carcinomatosis with metastases to the bones and other structures. At this time her blood gave a positive Fuchs reaction. She was pregnant and was delivered by cesarean section. No treatment was given for the malignant tumor. Two months later her blood gave a negative reaction. At this time she was much improved; she had gained weight and there was marked retrogression of her osseous lesions. However, several months later she died. There were twenty-seven patients whose blood gave negative reactions. These patients were cured, were under treatment or had lesions in the early stages of growth. There were also eighteen cases for which no explanation appears and the results of the Fuchs test must be assumed to be genuine false negative reactions. Five posi-

tive Fuchs reactions were obtained in spite of the fact that pathologists failed to find malignant tissue. The authors present data on thirteen cases in which no microscopic examination was made. Their experience has not confirmed that of other investigators that false negative reactions are seldom obtained but that false positive reactions may be obtained in a number of conditions, notably syphilis and tuberculosis. They feel that the accuracy of the method could be increased by improving the quality of the substrate and by frequent checking of its activity. The limitations of the test are that: 1. The growth must be more than six months old. 2. The patient should not have been operated on or have received radium or roentgen treatment for at least a month. 3. The tumor must be in a period of active growth.

BCG Vaccination Against Tuberculosis.—Baudouin summarizes the eleventh annual report of the subcommittee on tuberculosis of the National Research Council dealing with the value of the BCG vaccine against tuberculosis. The report is based on 20,000 vaccinations accumulated during eleven years. Appraisal of the immunity conferred by the Calmette-Guérin vaccine considered the comparative mortality and morbidity figures observed in 725 vaccinated (ages from under 12 months to 13 years) and 1,178 unvaccinated children all living in contact with sputum-positive persons and indicated a 51 per cent total mortality balance in favor of the vaccinated group and a favorable morbidity rate of 47 per cent. Judged by the duration of the immunity conferred, vaccinated children were found to possess a greater resistance to tuberculosis than the unvaccinated: for children under 12 months by 71 per cent, from 1 to 2 years by 54 per cent, from 2 to 3 years by 86 per cent, from 3 to 4 years by 66 per cent and from 4 to 5 years by 33 per cent. The decline in mortality, though regularly favoring the vaccinated group, was not as uniform as was expected. This is attributed to the small number of deaths in both groups (eleven and fifty-eight respectively). Among 9,000 vaccinated children born into or living in families free from tuberculosis and ranging up to 13 years of age, no negative reactions occurred. None of the 275 deaths that occurred among them were due to tuberculosis. The report recommends BCG vaccination for all children, especially for those born into a contaminated environment. Infants were always vaccinated during the first ten days after birth. Protection against tuberculosis afforded by the vaccine is stated to last for two or more years.

Tattooing for Pruritus Ani and Perine.—Turell points out that the rationale of therapeutic tattooing with mercuric sulfide is still undetermined but that the mechanical trauma produced by tattooing without the use of mercuric sulfide is ineffectual for the permanent control of pruritus ani. His experience with thirty-seven cases warrants the extension of this treatment. At present he tattoos not only those patients with intractable pruritus ani of long standing who failed to respond to established therapeutic measures but also patients who have pruritus ani that is recalcitrant to treatment regardless of the duration of the lesion and the few so-called psychoneurotic patients with cutaneous perianal changes consistent with pruritus ani. Selection of patients is important, as results show that tattooing with mercuric sulfide is apparently ineffective for pruritus that is primary in the perineum and posterior vulva but effective in those cases in which there was a spread of the pruritus from the posterior to the anterior perianal areas involving the perineum and the posterior portion of the vulva. The treatment has thus far proved of little value for pruritus vulvae either of undetermined origin or with superimposed dermatitis. Tattooing with mercuric sulfide is done in the presence of inflammatory and infectious disease of the preformed anal ducts, anal glands and the crypts of Morgagni. All anal lesions are always eradicated prior to tattooing. Redundant perianal skin, even in the absence of anal lesions, is removed to facilitate tattooing. Operation and tattooing are never done at one sitting because the primary operation may control the pruritus and because in the presence of open wounds the mercuric sulfide may get into the subcutaneous tissues and form mercuric proteinate, which is toxic because it is gradually absorbed. Among the

thirty-seven cases treated there were three cases of recurrence following tattooing but in no instance was the recurrent anal pruritus as intense as the original. In one of these there was also present a transient bilateral scaly dermatitis in the tattooed perianal region and an intermittent bilateral irritation caused by oil or grease laden clothes. These two factors were bilateral in distribution and, as the recurrent pruritus was unilateral, the author believes that an insufficient deposit of mercuric sulfide in the skin may have been responsible for the recurrence. The itching was very mild and inconsequential in character in the two other patients and treatment directed to the associated or underlying anal lesions (excision of an infected crypt and topical medication of a fissure) caused the pruritus to disappear. Studies now in progress appear to show that a pharmacodynamic degenerative effect on the cutaneous terminal nerve supply is produced by tattooing with mercuric sulfide which alters the capacity of the terminal nerve network to respond to adequate stimuli. The author believes that a critical attitude should be maintained until a large series of treated cases have been observed for a long time.

Nervous System in Sickle Cell Anemia.—Hughes and his collaborators present six cases of sickle cell anemia with cerebral complications, review the literature and discuss the pathologic changes. From the records of their cases and from twenty-five culled from the literature it seems that neurologic manifestations are frequent, the lesions are multiple and the location of the lesions is variable. The onset of symptoms is often sudden and extensive enough to cause grave manifestations such as convulsions, meningeal signs, pains, aphasia, paralyzes, coma and death. The prognosis following central nervous system lesions is poor, varies widely and is unpredictable. Frequently there are patients who have recurrent episodes in whom the symptoms and signs are referable to the nervous system. In these cases there is a tendency for the later attacks to be more severe. The cerebrospinal fluid observations are variable and often normal, although the patient has definite neurologic signs. Fluids which on first examination were normal may later become abnormal. The abnormalities of the cerebrospinal fluid consist of increased pressure, sickled erythrocytes, xanthochromia and protein and leukocyte increases. The cerebral lesions are varied and widespread. It is the authors' opinion that the central nervous system lesions are primarily intravascular. The most common changes found at necropsy are dilatation of peripheral blood vessels and congestion with sickled erythrocytes. Multiple thrombosis of smaller blood vessels in the same area is the rule. Other vascular lesions in the small vessels include infiltrative and degenerative changes in the vessel walls, perivascular edema, cellular exudation, hemorrhage and necrosis. The changes in the larger arteries and arterioles include intimal proliferation, fragmentation and reduplication of the intima, medial fibrosis

and hyalinization, and sometimes hemorrhage into the media, with pigmentary changes and calcification. The cortical and convolutional gray matter and to a less extent the white matter adjacent to it are involved. The spinal cord has been studied inadequately, but the meager evidence available reveals meningeal and vascular lesions and degenerative changes in ganglion cells comparable to those found in the cerebral cortex. The presence of elongated and multipointed sickled erythrocytes, the increase of leukocytes, nucleated red blood cells, macrocytes and platelets and in some cases venous back pressure due to obliterative changes in the arterioles of the lung and myocardial failure increase the normally slow blood flow through the small vascular channels of the cortex. The arterial changes are interpreted as being secondary to capillary and venous thrombosis. The pathologic observations correlate well with the clinical manifestations. The milder symptoms (headache, drowsiness, dizziness, minor meningeal irritation and temporary sensory and motor symptoms and signs) are probably explainable on the basis of vascular stasis and small thrombi with good collateral circulation. Confusion psychoses, mental changes, convulsions, aphasia, hemiplegia, paresthesias, delirium and coma may occur with more extensive lesions. Dilated vessels, occasional hemorrhages, edema of the fundi, localized facial swelling, dilated and thickened and tortuous temporal vessels, bulging fontanels and relief of headache following epistaxis indicate that cerebral stasis is present. The severe joint and osseous pains complained of commonly are probably due to vascular lesions, inflammatory reaction and irritation of nerve endings in these tissues. Some severe back pains and neck stiffness interpreted as meningeal may be articular in origin or due to lesions in tendons and muscles. Some severe chest and abdominal pains and pains in the skin and extremities are probably referred pains which are primary in the central nervous system or spinal ganglions. There is no specific therapy.

Hypertension in Diphtheria.—Rosenbaum reports two cases of hypertension occurring in the course of postdiphtheritic paralysis. The blood pressure increased as the paralysis progressed and gradually decreased as the paralysis cleared. Von Kiss was the first to observe hypertension in uncomplicated cases of diphtheria. He also reported an elevation of blood pressure in four of six fatal cases of postdiphtheritic paralysis. Clinical and electrocardiographic signs of severe cardiac damage were present in all the patients. They died with symptoms of cardiac failure, and at necropsy degeneration of cardiac muscle was demonstrated. There has been much speculation concerning the etiology of blood pressure changes in diphtheria. On the basis of their animal experiments Romberg, Passler, Brulius and Muller believed that in the acute phase of diphtheria the cause of death lay in paralysis of the vasomotor center in the medulla, with a consequent fall in blood pressure. They claimed that vasomotor paralysis, not myocardial weakness, was the chief cause of circulatory failure. According to this concept hypotension is due to toxic injury to the vasomotor center, and hypertension is caused by its stimulation. The explanation of hypertension through increased cerebral pressure and consequent marked compression of the medullary centers would be completely understandable. The experiments of Friedemann, who found increased spinal fluid pressure without increased protein or cells as a constant symptom in severe diphtheria, support this concept. However, Von Kiss and Horanyi were unable to demonstrate anatomic changes in the vasomotor centers. They felt that the vegetative nervous system of human beings, guinea pigs and horses did not have affinity for diphtheria toxin. Attempts to correlate the pathologic urinary changes in some cases of diphtheria with changes in blood pressure have shown no relationship. Rosenbaum believes that in these cases a neurologic etiology would seem most tenable. He cites three cases reported by Salus. In the two patients who survived, the hypertension, marked lability of pressure, tachycardia and increased respirations came on with the ascending paralysis when the bulbar symptoms appeared, and they gradually cleared as the paralysis improved. Muller and Nordmann encountered a similar case in which a lesion was found in the substantia reticularis grisea to which the hypertension was attributed. The author says that these cases of paralysis with hypertension bear a striking resemblance to his two cases

of postdiphtheritic paralysis. In all of them the symptoms of hypertension came on at the same time as the paralysis and gradually cleared as the paralysis improved. As all these patients showed either hypoglossal or vagal paralysis, the hypertension might be due to irritation of the neighboring glossopharyngeal nerve, such as is seen in glossopharyngeal neuralgia. This reflex is mediated through the carotid sinus.

Thoracoplasty for Pulmonary Tuberculosis.—Miller and his colleagues discuss their experience with 245 thoracoplasty stages or operations necessary for 100 consecutive patients with parenchymal disease. There were twenty-six cases complicated by tuberculous empyema and two by a persisting pleurisy with effusion. One was an oleothorax case and one a pneumothorax which would not reexpand. Seventy-five per cent of the patients operated on were between 20 and 40 years of age. Only thirty-five of the cases were strictly unilateral, while sixty-five presented bilateral disease; twenty-one required contralateral collapse procedures. The disease was moderately advanced in only 20 per cent of the patients. Thoracoplasty was performed on the right side in forty-four cases and on the left side in the remainder. The disease was predominantly exudative on the operative side in 25, exudative and productive in 70 and productive in 5 per cent. In sixty-five cases the disease was present in the opposite lung. Cavitation was present in eighty-three of the 100 cases, confined to one lobe in seventy-eight. Complete closure was effected in sixty-four of the eighty-three cases. The results of thoracoplasty indicate that contralateral disease is no contraindication to thoracoplasty, provided it is not extensive or unstable or that it is brought under control by some form of collapse. There was little or no difference in the ultimate result whether the disease was contralateral or not; 85 per cent of both classes showed definite improvement, whereas 50.8 per cent of the former and 43 per cent of the latter were apparently arrested or apparently cured. Contralateral compression should be considered as a means of preparing serious cases with bilateral disease for thoracoplasty operation. Thoracoplasty should not be instituted only as a last chance measure but should be considered

for good risk patients, when the disease is unilateral or at most slight in amount and well fibrosed in the contralateral lung. In good risk patients the disease is inactive and the patient's general condition is good. The smaller cavities were more easily and more frequently closed than the larger ones, which also holds true in other forms of collapse therapy. The likelihood of complete closure is greater in the thinner walled cavities. A good mechanical result does not always mean that the patient is free of symptoms or bacilli. However, none of the patients with good mechanical results (73 per cent) have died. The ones that were not cured or arrested were converted from a state of "poor chronicity" to one of "good chronicity" or with the passage of time they may be cured. On the whole, the patients with cavities did better than those with no cavities, with the exception of the mortality rate. If the empyema cases are eliminated, the noncavity cases lead by a good majority. The results were slightly better among patients with negative sputum, but so little better that it is somewhat surprising. The chance of a good mechanical result was lessened, as was also the chance of a good clinical result, as the delay between operative stages lengthened. The usual interval between operations was two weeks. Practically as good results were obtained among the older cases as in those of shorter duration. However, the best results were obtained in those patients whose disease existed for less than a year. There were eleven deaths, and only six were classified as operative deaths. Contralateral spread of the infection occurred in fifteen patients and wound infection in five; other mild or serious complications occurred in thirteen. The authors hope that, now that spinal anesthesia is being used rather extensively, the number of spreads will be reduced materially. The cause of spread, they believe, is usually due to failure to cough up secretions immediately after operation, with resultant pooling in the opposite lung. Thoracoplasty has left something to be desired, as only nine patients can be classified as cured, forty as arrested and thirty-six as improved. Only four were not improved by operation, and as eleven died the operation was unsatisfactory in fifteen.

Observations on Pruritus Ani.—Speare and Mabrey discuss the various treatments tried in 175 cases of pruritus ani encountered during the last four years at the Rectal Clinic of the Massachusetts General Hospital. The age of the patients varied from 18 to 80 years. There was only one patient less than 20 years of age, while the third, fourth, fifth and sixth decades were about equally represented. The ratio of men to women was almost 2:1. The reason for this is probably the more scrupulous hygiene that women employ after defecation. The duration of symptoms varied from one week to thirty years. Local disease, which consisted chiefly of internal hemorrhoids and external skin tags, was present among 40 per cent of the patients. Cutaneous itching in other parts of the body was complained of by nineteen of the 175 patients. There is no specific treatment for pruritus ani, and therefore every patient should be treated individually by one method or a combination of several methods. Scrupulous hygiene is of paramount importance. This includes washing with soap and warm water after every defecation, and thorough drying without excessive rubbing. Various soothing, astringent, antiseptic, keratolytic or antipruritic topical medicaments were used. Most patients respond to one or another of these. Many simple early cases can be cured with nothing more than careful hygiene. Acute stages of erythema, excoriation and vesication without chronic cutaneous changes can be made to disappear in one or two weeks by the daily application of tincture of metaphen. Even patients with signs of an acute dermatitis superimposed on chronic cutaneous changes should be so treated. For chronic cases showing thickening and cutaneous discoloration without superimposed acute irritation, keratolytic and antipruritic ointments should be used. The application of salicylic acid and sulfur ointment is effective. Scrupulous hygiene and continued use of this or a similar ointment may bring about permanent improvement. When all simple treatments fail some form of subcutaneous injection is resorted to in order to interrupt the afferent sensory pathways. Forty-eight patients required injection treatment. For eighteen a solution containing quinine and urea hydrochloride and procaine hydrochloride was used, an oil-soluble anesthetic for sixteen and alcohol for fourteen. Injection treatment should not be carried out in the presence of acute exacerbations. Of the injection measures 70 per cent alcohol injected subcutaneously gave the best results. Roentgen therapy was used for four patients; one obtained relief for seven weeks, one for three weeks, one had no relief and one had partial relief for a year.

Treatment of Gonococcal Infection in Women.—Brunet and his associates compare the results of 241 gonorrheal infections in women treated with silver proteinate instillation and local treatment with the results among 241 similar cases in which sulfanilamide and local treatment were given. The study shows that the latter management halves the distressing pelvic complications and reduces the treatment period by a third. There was an increase in the number of abscesses of Bartholin's gland, but the authors can give no satisfactory explanation for this finding. The reactions to sulfanilamide were numerous but usually of a minor nature. Seventeen per cent of the patients were unable to take 40 grains (2.6 Gm.) of the drug without disturbing reactions. However, the patients who were able to take only 20 grains (1.3 Gm.) of sulfanilamide daily made almost parallel progress with those taking larger doses. The authors have no satisfactory explanation for this observation, unless the concentration of the drug in the blood does not have the significance previously attributed to it in relation to the control and cure of gonorrhea.

Helium-Oxygen Mixtures for Tubal and Sinus Block.—Crosson and his co-workers encountered in a course of a field study on compressed air illness a by-product, namely ear block or tubal and sinus block. Helium-oxygen mixtures are a means for its relief. This subjective complaint of pain or discomfort in the ears is a distinct entity encountered in compressed air work and is entirely separate from compressed air illness. Armstrong and Heim observed the same condition in aircraft pilots. In compressed air workers the condition may advance to a frank otitis media if the block is not relieved promptly. The ears may not be involved, but an obstruction of one or more of the ostiums of the accessory nasal sinuses may produce severe pain in the area of the affected sinus. The only objective sign in sinus block may be slight nasal bleeding. If relief is not afforded, the pain continues and an acute sinusitis is likely to develop. Tubal and sinus blocks are most commonly encountered in workers with infection of the upper part of the respiratory tract. In "locking in" the compressed air worker must consciously or unconsciously continuously equalize the pressure in his accessory sinuses and middle ear. Many workers swallow while locking in, but the majority use the Valsalva method, closing the nose and mouth tightly and attempting to expire forcefully, thus increasing the pressure in the pharynx and forcing air up to the middle ear by way of the eustachian canal. If one man of a gang acquires a "block," the intruding air must be shut off at once and the pressure lowered. Then a second try is made and, if not successful this time, the worker must leave the lock. This fluctuation of the pressure often precipitates a "block" in one or more men of the gang attempting recompression after the first worker has been "locked out." Oftentimes, rather than lose a shift or be ridiculed by his mates, a worker will "force himself through," by enduring the pain and discomfort in the hope that it will soon right itself. These are the cases in which otitis media, often with subsequent suppuration, and rupture of the ear drum are more prone to develop. If the worker reports to the physician on duty, a series of shrinking solutions will be placed far back in his nose and throat, which may or may not be efficacious in breaking the block. A method of eliminating these conditions with helium was tried out. A helium-oxygen mixture should diffuse through an accessory nasal sinus ostium or the eustachian tube more rapidly than would the nitrogen of air. Thus the equalization of pressure between the middle ear and the external barometric pressure should occur more readily. A simple apparatus was designed by the United States Bureau of Mines Laboratories which could be used by the worker in the man lock. It consists of a small cylinder of 80 per cent helium and 20 per cent oxygen connected through a small reducing valve to a "lung" or breathing bag. The breathing bag is equipped with an admission valve, and attached to it is a rubber tube with a detachable face mask. The whole apparatus is no larger than a small suitcase and can be left permanently in the man lock in charge of the lock tender. The apparatus is automatic and ready for instant use. The affected worker applies the mask and breathes normally for one minute or more and usually the "block" is broken. He can then go on through either still using the mask or not as necessity demands. The authors believe

that this procedure should save considerable time for the worker and the employer and obviate the danger and discomfort of the disabling tubal or sinus block. The use of this apparatus in the man lock is strongly urged in order to prevent the occurrence of the more serious complications of "block" and also as it will obviate the necessity of fluctuation of pressure which frequently precipitates a "block" in one or more men attempting recompression after the first worker has been "locked out."

Pancreatectomy for Hypoglycemia.—David discusses the advisability of partial or subtotal resection of the pancreas for hypoglycemia when no neoplasm is found in the part removed. Of eighteen partial resections (from 14 to 28 Gm.) with no tumor, the pancreas of fifteen patients was normal histologically and in three hyperplasia of the islet cells was present. The minimal blood sugar in this group was below 50 mg. per hundred cubic centimeters in fourteen patients. Of fourteen surviving patients only three were free from attacks, three were moderately improved and the attacks of eight continued. Seventeen other patients have had from 35 to 60 Gm. of pancreas removed for spontaneous hypoglycemia. No tumor was found in the resected tissue in these patients. The examination of the pancreatic tissue revealed fourteen normal pancreases, hyperplasia of the islet cells in two and a pancreatitis in one. Eleven of these patients are relieved of the symptoms of hypoglycemia. Seven have been followed for more than two years. There was only one operative death. Of the four unimproved patients, two had a fasting blood sugar of from 65 to 70 mg. per hundred cubic centimeters before the operation and therefore may not strictly belong to the group giving the characteristic Whipple triad of symptoms (attacks of nervous or gastrointestinal disturbances coming on in a fasting state, a hypoglycemia with readings below 50 mg. and immediate relief from the ingestion of dextrose). The author concludes that exploration of the pancreas is indicated in patients with this triad of symptoms in whom extrapancreatic causes of hypoglycemia have been excluded and dietary management has failed. Subtotal resection of the tail and body of the pancreas up to the superior mesenteric vessels is indicated when exploration reveals no tumor.

This operation should be a part of the treatment of spontaneous hypoglycemia until more knowledge of the underlying causes of the condition offers a better solution of the problem.

Lung Tissue Necessary for Life.—Graham reports the removal from a boy of 14, because of bronchiectasis, the two lower lobes, the right middle lobes and the lingula of the left upper lobe. It is generally accepted that the lingula is the homologue of the right middle lobe. Therefore the case represents the removal of four of the six lobes and, according to the literature, is the most extreme example of successful radical removal of pulmonary tissue. Although only two months has elapsed since the completion of the second operation, the boy is able to walk rapidly for short distances without dyspnea and his vital capacity is 1,200 cc. Continued improvement and increase in vital capacity are expected. After the first operation, on the right side the boy's expectoration was decreased by one half and cough was confined to mornings and evenings. Since the second operation there has been no cough or sputum and severe clubbing of the fingers has disappeared. The patient's productive cough followed an attack of pneumonia at the age of 2½ and continued until the second operation, after which there has been no cough or sputum.

Hemophilus Influenzal Meningitis Cured by Sulfathiazole: Case. A. J. Aballi.—p. 349.

Erythema Nodosum.—Erythema nodosum, according to Silva, is now preponderantly regarded as of tuberculous origin. The various criteria employed to determine tuberculous infection—a contaminated environment, positive tuberculin tests, roentgenograms, the detection of bacilli in the nodules and blood and the examination of the gastric contents during fasting—combine to yield corroborative evidence. In one of his eight cases (age level from 11 months to 8 years) the positive Mantoux reaction was delayed for three weeks. The author thinks that x-ray examinations should be regularly performed because of the frequent involvement of lymph node and pulmonary tissue even if the physical examination remains negative. The type of lesion usually found is an epituberculosis, a serofibrinous leukocytic inflammatory reaction occurring about the focus of the tuberculous infection. The prognosis is quite benign. A full bibliography is presented.

- *Significance of Asymptomatic Renal Calculus in Anemia. R. Gutiérrez.—p. 419.
Necessity of Pharmacodynamic Study of Mexican Plants. E. C. del Pozo.—p. 438.

Anemia Due to Unsuspected Renal Calculus.—Gutiérrez discusses the etiology of asymptomatic kidney stone, the pathogenesis of secondary anemia and the patient's amelioration following nephrolithotomy, in some cases with complete recovery from anemia and from gastrointestinal symptoms. Case histories, of which seven (age level from 23 to 58) are selected for comment, showed common symptoms and signs of anemia, such as loss of appetite, weight and vigor, gastrointestinal disorders, fatigability, abnormal blood picture and the total failure of antianemic medication, however long sustained, to improve the patient's condition, in the absence of correct diagnosis and surgical intervention. Latent renal concretions, though persisting for years, may remain completely undetected until necropsy. The absence of symptoms, negative results in routine urine examinations, even when one of the kidneys is completely blocked, and negative roentgenograms in the presence of radio-transparent calculi contribute to confuse diagnosis. Some latent calculi can ultimately be determined only by retrograde pyelographic tests. The author reviews the various factors productive

of kidney stone. The degree of severity of secondary anemia depends on the extension, site and duration of the calculus as well as on the type of pathogenic organism involved. Frequently renal calculus is associated with tumor or renal tuberculosis. Most calculi are found in patients with alkaline urine. So-called idiopathic anemia may be due to calculus and its secondary character completely mistaken. The presence of "staghorn calculus" points to a long history of stone formation. The author believes that patients with refractory anemia should be subjected to full urographic examinations. Anemia due to nephrolithiasis is scantily treated in the literature.

*Perforating Cholecystitis. V. de Angelis.—p. 445.
Preoperative and Postoperative Mental Reactions. Y. dos Guarany's.—p. 463.

Perforating Cholecystitis.—De Angelis reports eight cases of cholecystitis with perforation into the peritoneal cavity. The patients were between the ages of 27 and 30 years, except one, who was over 40. He states that the most frequent cause of this type of perforation is lithiasis and infection of the bile tracts with bacteria of the typhoid or coli groups. The symptoms are those of acute inflammation of the right side of the abdomen from rupture of a hollow viscus. The earlier the operation, the better the prognosis. Peritonitis develops with such rapidity that the majority of the patients are seen in the course of a more or less acute peritonitis. A preoperative diagnosis of rupture can be made from the seat of the lesion, as indicated by the localization of pain and muscle spasm over the gallbladder area, verified by pneumoperitoneum. The treatment consists in cholecystectomy with subhepatic drainage. The author prefers general anesthesia with nitrous oxide or cyclopropane to ether. The latter causes diminution in the secretion of bile. Lack of the flow of bile from the perforation may cause one to overlook the perforation with later effusion of bile taking place into the peritoneal cavity. Cholecystectomy with subhepatic drainage is indicated in obvious perforation of the gallbladder with bile in the peritoneum as well as in spontaneously closed perforation. Cholecystectomy is indicated even in the presence of sterile cultures from bile effusion, since the fluid may become infected later. Cholecystostomy with drainage in cases of spontaneously closed perforation is dangerous, as it may give rise to recurrent perforation.

*Treatment of Suppurative Lesions with the Balsamic Pack of Vishnevskiy. V. I. Parmenov.—p. 143.
*Transfusion of Cold Conserved Blood. A. N. Glinskiy.—p. 151.

Suppurative Lesions.—Parmenov reports the results obtained in 251 cases of suppurating wounds treated with an ointment proposed by Vishnevskiy. The composition of the ointment is juniper tar 5 parts, bismuth tribromphenate 2 parts and castor oil 100 parts. The ointment appeared to be most effective in the acute, deep and extensive suppurations of soft tissues, such as one sees in perinephric abscess, pectoral phlegmon, intramuscular suppurations of the neck, buttocks or the hand. Rapid detoxification, abundant granulations and sharp decline in the amount of pus were observed as a rule in this group. The ointment was applied in cases of acute hematogenous osteomyelitis with good effect. In pyemia, local treatment with the "balsamic pack of Vishnevskiy" was combined with transfusions of small amounts of conserved blood. Observations in twelve cases of chronic varicose ulcers of the leg demonstrated that the ointment is of little if any effect in the treatment of superficial chronic ulcerating surfaces. The author adhered in the treatment of extensive wounds to the principle of wide exposure under anesthesia and careful and meticulous débridement, after which the wound was gently packed with tampons saturated with the balsamic ointment. No toxic effects on the kidney were noted.

The packs are left undisturbed for from four to nine days depending on the extent and depth of the wound. The author attaches great importance to the immobilization of the suppurating focus in a plaster of paris cast. Physical therapy, streptocid (a sulfonamide), calcium, dextrose and methenamine and blood transfusions in grave cases were regularly employed. The author was impressed with the effect of the ointment on the general condition of the patients, the rapid fall in temperature, excellent granulations, rapid sloughing and healing of the wound. He considers the Vishnevskiy ointment superior in the treatment of extensive suppurations to the method of Carrel-Dakin.

Transfusion of Cold Conserved Blood.—Glinskiy failed to observe any alteration in the respiratory or cardiac function in animals following transfusion of cold conserved blood. He studied the effect on erythrocytes of warming blood conserved in a citrate solution. Portions of blood were warmed to 10 or 12 C., to 20 C. and to 30 and 40 C. Warming the blood to 12 and to 20 C. had no effect on the shape and on the osmotic resistance of the erythrocytes. In preparations of blood warmed to 30 and to 40 C. there were observed changes in the shape and the size of erythrocytes with the appearance of microcytes and shadows of erythrocytes and diminution in their osmotic resistance. The breaking down of the red cells under the influence of the warming up process proceeded parallel with the time of conservation of the blood. Beginning with January 1939 the author had performed 214 transfusions of conserved blood without resorting to warming. The temperature of the blood was from 10 to 12 C. In this group there were 26.1 per cent of clinically manifested reactions as contrasted with 38 per cent of reactions observed by the author in a previous group of 1,400 transfusions of blood which was warmed preliminary to transfusion. The author points out that the method of transfusing conserved blood without warming should be of particular significance in military practice.

*X-Ray Examination of Kidney Injuries with Special Regard to Intravenous Urography. I. Hareide.—p. 292.
Division of Lung Segments. E. Huizinga and E. Behr.—p. 314.

X-Ray Examination of Kidney Injuries.—Hareide points out that intravenous urography is indispensable in diagnosing kidney injuries and observing their anatomic nature. The roentgenogram and the urogram both give valuable information. The former enables one to recognize perirenal hematomas or an enlargement of the kidneys in case of subcapsular injuries. The latter gives information about the condition of the renal pelvis and about the respective functioning of the injured and uninjured kidney. The intravenous urogram is not as informative as the retrograde pyelogram but is sufficient as a rule to demonstrate the anatomic changes. Conclusions as to treatment drawn from roentgenologic observations should be compared with the clinical observations. Large perirenal hematomas do not indicate surgical intervention as they seldom endanger life. Likewise contrast mass outside the renal pelvis gives no indication for surgical intervention in case the extravasated urine lies in the kidney parenchyma. Should one observe, on the other hand, the contrast mass outside the kidney, the prospects of spontaneous cure are less encouraging. Cases without contrast mass excretion are the hardest to examine. There are roentgenologic signs that indicate whether the lack of secretion is due to a more or less serious cause. In case the kidney shadow is clear and of normal aspect the lack of secretion cannot be caused by a lesion of the renal artery or an extensive destruction of the renal tissue. The causative factor will most likely lie in the ureter in the form of an impediment to the flow of urine. If on the other hand the roentgenogram reveals a large retroperitoneal hemorrhage there is a possibility that the kidney has been destroyed. In such cases the clinical symptoms will decide whether immediate surgical intervention is necessary or whether one should wait and repeat urography later.

SHOULD SOLUTION OF POSTERIOR PITUITARY BE USED

IN THE FIRST AND SECOND STAGES OF LABOR?

JOHN A. SHARKEY, M.D.

PHILADELPHIA

The term solution of posterior pituitary employed in this paper includes pituitrin, pitocin, infundin, thy-mophysin, pitanthym and all other preparations depending for their action on the oxytocic principle of the posterior portion of the pituitary gland.

Since its discovery and introduction into medicine, much has been written about solution of posterior pituitary.¹ It is a powerful drug. In addition to its oxytocic and pressor effects, clinical hypersensitiveness has been reported occasionally.²

As the result of investigations of the Maternal Welfare Committee of the Philadelphia County Medical Society over the past nine years and of the Committee for the Study of Stillbirths of the Obstetrical Society of Philadelphia over the past three years, I have collected some data regarding the use and abuse of this uterine stimulant in the first and second stages of labor. This paper summarizes my impression of the use of the drug in normal labor, uterine inertia and complications of pregnancy.

NORMAL LABOR

The use of solution of posterior pituitary in normal labor places a grave responsibility on the physician. He administers it to accentuate pains and hasten delivery with, as Mendenhall remarks, "unfortunately more benefit to himself than to the mother and baby."

The Committee on Fetal Mortality of the Philadelphia Obstetrical Society studied 1,000 stillbirths between Oct. 1, 1937, and March 31, 1939, and found twelve cases in which death of the baby in normal labor could be ascribed to the use of solution of posterior pituitary. In eight of these cases delivery was done in hospitals and in four in the home. Two of these twelve babies showed intracranial hemorrhage at autopsy. In the remaining ten autopsies were not held but the committee, after careful discussion, felt justified in ascribing the deaths to the use of solution of posterior pituitary in labor. It is fair to assume, considering the work of Bundesen and his co-authors,³ that more autopsies would have revealed at least a few more intracranial hemorrhages.

Read before the Section on Obstetrics and Gynecology at the Ninety-First Annual Session of the American Medical Association, New York, June 12, 1940.

3. Bundesen, H. N.; Fishbein, W. L.; Dahms, O. A., and Potter, E. L.: Factors Responsible for Failure Further to Reduce Infant Mortality, *J. A. M. A.* 109: 337-343 (July 31) 1937.

Naturally, no method of ascertaining how often these oxytocic preparations were used in the remaining cases in which delivery was done in the city of Philadelphia during the period covered by the report, but there is unmistakable evidence of an occasional neonatal death resulting from their use in normal labor.

The following hospital delivery is illustrative:

Mrs. M. N., aged 28, had one previous normal delivery. Labor began at 1:10 p. m., Sept. 24, 1937, and progressed slowly but normally until 11 a. m. the following day. A left occipito-anterior position with four fingers' dilatation of the cervix was found on examination, and the attending obstetrician administered 0.75 cc. of solution of posterior pituitary at 11:18 a. m. After one long, continuous hard uterine contraction, accompanied by a heavy flow of blood, the head with intact membranes crowned at the vulva. The membranes were ruptured manually and the child was born twenty-one minutes after the administration of 0.75 cc. of solution of posterior pituitary. The child was in poor condition, difficult to resuscitate and edematous and had rapid grunting respirations, high pitched cry, contracted, nonreactive pupils, restlessness and twitching. Severe cyanosis and atelectasis developed. The baby died the following day. Cerebral cranial traumatism, partial atelectasis and aspiration pneumonia were disclosed at autopsy.

Dugger,⁴ in reviewing ninety cases of rupture of the uterus studied by the Maternal Welfare Committee of the Philadelphia County Medical Society, found four cases of ruptured uterus resulting from the use of pituitrin in labor.

The following case from the files of the Maternal Welfare Committee of Philadelphia illustrates what may happen when solution of posterior pituitary is given by the physician with the idea of saving his time:

Mrs. A. C., a white woman aged 36 in her tenth pregnancy, fell into labor at 3 a. m. on Dec. 19, 1937. The patient had arranged for home delivery. She was given an ampule of solution of posterior pituitary at 10 a. m., and after that several attempts were made to apply forceps. Forceps failed and the patient was brought into the hospital at noon because of vaginal bleeding and obstructed labor.

On arrival at the hospital the patient was not in labor, the head was not engaged and the cervix was only 2 cm. dilated. At 6 p. m. the patient was again having good uterine contractions, the head was engaged and the cervix was 6 cm. dilated and fully effaced. By 11 p. m. the head was in midpelvis and the cervix fully dilated, but the uterine contractions had become very weak and irregular. At 7 a. m., December 20, the patient was again having good contractions and the head was almost on the pelvic floor. At 8:15 a. m. the patient complained of severe pain in the right lower quadrant, and labor ceased. The pulse became rapid and the patient showed signs of shock. A diagnosis of ruptured uterus was made and a Porro section performed. During the operation 500 cc. of blood was given. For the first few hours after the operation the patient was in fairly good condition, but during the night she became very distended and began to vomit. Another 500 cc. of blood was given, but the patient became progressively worse and died at 12:30 p. m., December 21. Postmortem examination revealed

4. Dugger, J. H.: Personal communication to the author.

markedly distended intestines with diffuse inflammation of the peritoneal surfaces. The baby weighed 9 pounds 5½ ounces (4,238 Gm.) and x-ray examination showed a compression fracture of the right parietal bone.

This patient probably would have delivered spontaneously if labor had been allowed to progress without interference. It is to be regretted that incidents such as this continue to occur.

Spontaneous labor often causes intracranial hemorrhage in the baby, resulting in stillbirths and neonatal deaths. In the Holland and Lane-Clayton⁵ report 520 spontaneous deliveries, eighty-seven babies had tentorial tears, forty of which occurred in 299 normal vertex presentations. If this is true of spontaneous delivery in which solution of posterior pituitary is not used, how much more must it be true when the uterus is made to contract violently. These violent contractions may occur with even small doses, for when labor starts the uterine muscle is peculiarly sensitive to the action of this drug. When a baby is driven through the birth canal so rapidly that it has no chance to accommodate itself to the various diameters of the pelvis, tears of the falx cerebri and tentorium cerebelli are bound to occur. Again, tetanic contractions of the uterus interfere with placental circulation and with the blood supply of the uterus, resulting in fetal asphyxia and damaging uterine musculature. There is also the danger of deep cervical and perineal lacerations, injuries to the birth canal, premature separation of the placenta, postpartum hemorrhage, shock and collapse and, finally, rupture of the uterus.

However often it has been emphasized that solution of posterior pituitary should not be used in normal labor, there remains the impression that it is in this condition it is used most widely; and the reports of maternal health committees and government agencies confirm this.

UTERINE INERTIA

Uterine inertia is a term used to describe weakness and irregularity or infrequency of uterine contractions during labor. It may be due to mechanical causes or to some deficiency in the uteromusculonervous mechanism, the so-called true primary inertia. It is usually classified as primary and secondary.

1. *Primary Inertia*.—In the past seven years, in a series of 10,241 successive ward and private deliveries in the Misericordia and Fitzgerald-Mercy hospitals, Philadelphia, solution of posterior pituitary was employed in eighteen cases of primary uterine inertia. All the patients were given small doses of pitocin in the first stage of labor before the cervix was fully dilated. All were vertex presentations. There were twelve primigravidas and six multigravidas; the youngest patient was 25 years of age, the oldest 35, the average being 29. Average hours of labor were thirty-five; the average dose of pitocin was 4½ minims (0.27 cc.), the smallest dose was 1 minim (0.06 cc.), the largest was 18 minims (1.12 cc.) given in six doses of 3 minims (0.18 cc.) each. All had operative deliveries. Three were delivered by episiotomy alone, twelve had episiotomy and forceps, four of the forceps operations were midpelvic applications. Seven of the patients were morbid. There was no maternal mortality. One baby was stillborn.

In my opinion, solution of posterior pituitary has a limited but helpful place in the first and second stages of labor complicated by primary inertia. The following case is illustrative:

Mrs. M. O., a primigravida aged 35, was in excellent health but fearful of labor. The head was deep in the pelvis two weeks before delivery. After two and one-half days of weak, irregular pains the cervix was only 2 cm. dilated, effacement was not complete and the membranes were intact. The patient had been adequately rested, but had a temperature of 100 F. Three minims (0.18 cc.) of pitocin was administered. Forceful pains ensued, and in eighteen hours dilatation was complete and delivery accomplished by low forceps. The mother and baby were discharged in good condition on the sixteenth day post partum.

Three of our patients with primary inertia were delivered by cesarean section. One had premature rupture of the membranes and weak, indifferent pains. This patient had a total of 18 minims (1.12 cc.) of pitocin in six doses of 3 minims (0.18 cc.) each at intervals of twenty minutes. After eighteen hours of ineffective labor a cesarean section was performed and myoma uteri revealed as the cause of the inertia. This patient had a stormy convalescence, the abdominal wound breaking down, but she finally recovered.

The second cesarean section was done after the patient had been in labor thirty-two hours and had been given two doses of pitocin of 3 minims (0.18 cc.) each.

The third cesarean section was performed after the patient had been in labor forty-three hours. Four doses of pitocin of 2 minims (0.12 cc.) each were given during labor. The baby was stillborn. At operation it was noted that one-half of the uterus was contracted while the other half was relaxed. The latter two were the only patients in this series with true primary inertia in whom the drug failed completely.

Tollefson and Webb⁶ are enthusiastic regarding the use of solution of posterior pituitary in uterine inertia and state that, "while oxytocics indiscriminately used are dangerous, in this series their efficiency was unquestionable." Garber⁷ is only lukewarm in his attitude. Bell,⁸ after advising rest, enemas and occasionally rupture of the membranes when the os is three parts dilated, states that "the administration of pituitary extract is indicated; it does no harm and in many cases is definitely beneficial." Davis⁹ states, "Rarely is it advisable to give solution posterior pituitary for uterine inertia. If this is done, the dosage should be limited to 1 or 2 minims subcutaneously. This should not be repeated many times." Schumann¹⁰ states that, "if the birth canal is clear for the passage of the fetus which lies in a normal presentation and position, the uterus may be stimulated even though the cervix is not fully dilated and effaced. The only drug here is pituitrin."

The use of solution of posterior pituitary should be limited to cases of true primary inertia. These are the cases in which there seems to be actual weakness of the contractile muscle or of the uteromusculonervous mechanism, though the real cause of the difficulty is still unknown. Cases of normal labor have been reported

after presacral sympathectomy, and De Lee¹ mentions a case of Elkins in which a paraplegic patient had a spontaneous delivery. Vaux¹¹ states that this type of inertia is extremely rare. It is likely to occur in elderly primiparas of the nervous emotional type, in elderly multiparas with long intervals between pregnancies, in women whose obesity arises from endocrine dysfunction, in anemic or asthenic women, in chronic invalids, in convalescents from acute infections and in those undernourished from hyperemesis gravidarum. Those women represent a small group as a whole and not all of them will exhibit uterine inertia.

Solution of posterior pituitary should not be used when uterine inertia is due to the following mechanical causes:

- (a) Generally contracted pelvis.
- (b) Abnormal positions of the fetus, as persistent occiput posterior, breech, shoulder, face or deep transverse arrest of the vertex.
- (c) Tumors of the uterine wall or other tumors in or near the uterus blocking the birth canal.
- (d) Congenital anomalies such as bicornate uterus or infantile uterus.
- (e) Abnormal positions of the uterus, as retroflexion or ante-flexion with pendulous abdomen.
- (f) Great multiparity causing thinning of the uterine wall with the danger of spontaneous rupture of the uterus.
- (g) Overdistention of the uterus, as in polyhydramnios, and multiple pregnancies.
- (h) Scars in the uterus from previous operations or disease of the uterine wall.
- (i) Dystocia dystrophica syndrome.
- (j) Rigid cervix, undilatable.

A critical examination of the list of causes just given will show that operative intervention will often be necessary to accomplish delivery and that in the treatment of uterine inertia the underlying condition is the important factor.

2. Secondary Inertia.—In my opinion, solution of posterior pituitary should not be used in secondary uterine inertia when the uterine muscle is exhausted after many hours of hard labor. Sedatives, rest and maintenance of nutrition to prepare the patient for operative delivery or a further test of labor is advisable.

Certainly solution of posterior pituitary has no place in the treatment of Bandl's contraction ring, strictura uteri and tetanus uteri.

When the second stage of labor is unduly prolonged because of the failure of weak uterine contractions to expel the fetus, presentation being normal and rotation completed, it is perhaps wise to terminate labor with low forceps. I realize, however, that in home deliveries, because of lack of facilities, it is not always possible in cases of mild inertia to do outlet forceps operations. Under these conditions solution of posterior pituitary may be used in lieu of forceps, preferably in multiparas, and in doses of 1 or 2 minims (0.06 or 0.12 cc.). In fact, this is the only instance in which the American Committee on Maternal Welfare¹² recommends the use of solution of posterior pituitary in the first two stages of labor.

COMPLICATIONS OF PREGNANCY

1. Toxemias of Pregnancy.—In toxemic patients, solution of posterior pituitary should not be used because of its potential dangers. It has been shown that the

blood pressure may rise an average of 51 mm. of mercury after the misdirected use of the drug in toxemias and that it may reduce diuresis and cause convulsions or pulmonary edema if the patient is edematous.¹³

2. Abruptio Placentae.—Solution of posterior pituitary in conjunction with the abdominal binder has been recommended in the treatment of abruptio placentae. This treatment should be administered only by a skilled obstetrician with sound judgment.

3. Placenta Praevia.—If intrapartum hemorrhage is due to low implantation of the placenta, solution of posterior pituitary will not control the bleeding and the drug should not be given for this purpose.

4. Heart Disease.—Solution of posterior pituitary should not be used in serious heart disease because of the danger of reactions and the added strain placed on the heart should the labor become severe following the injection of the drug.

DOSAGE

The dose of solution of posterior pituitary should always be small and should not exceed 3 minims (0.18 cc.). If one prescribes unit doses, the standard preparations are marketed with 10 international units per cubic centimeter or two-thirds unit per minim. Murphy's¹⁴ studies on the pregnant uterus at term with the Lorand tocograph indicate that, if tetanic contractions are to be avoided, the dose has to be kept below 1½ minims (0.09 cc.), preferably 1 minim (0.06 cc.), and that there should be an interval of thirty minutes between doses.

The drug should be stopped when uterine contractions start. Too violent or long continued contractions must be controlled by the administration of an anesthetic. If the tetanic contractions cause fetal distress and delivery is imminent, labor should be terminated by forceps.

The drug may also be administered as recommended by Hofbauer;¹⁵ i. e., by the use of nasal packs saturated with 0.5 cc. of the solution. The cotton may be removed and the nose flushed with saline solution if the contractions become too violent.

CONCLUSIONS

1. The use of solution of posterior pituitary to accentuate the pains of normal labor and to hasten delivery is to be condemned.

2. Solution of posterior pituitary may be used with care and discrimination:

(a) In certain cases of true primary uterine inertia after having satisfied oneself that no mechanical hindrance to delivery is present.

(b) In lieu of low forceps to terminate labor when the second stage is unusually long because of weak pains and there are no facilities to deliver by forceps.

(c) In abruptio placentae by those who possess sound obstetric judgment and operative skill.

3. The dose should never exceed 3 minims (0.18 cc.) and is preferably 1 minim (0.06 cc.). Intervals between doses should be at least thirty minutes. This dose is not to be repeated if good contractions start.

ABUSE OF SOLUTION OF POSTERIOR PITUITARY DURING EARLY LABOR

GEORGE F. PENDLETON, M.D.

KANSAS CITY, MO.

I do not favor the use of solution of posterior pituitary during early labor.

Even my opponents admit that large doses at improper times may cause rupture of the uterus. They claim, however, that small doses given when there is no obstruction to hinder fetal advancement are safe and that still smaller doses can be used during the first stage of labor without any harm whatever.

In any labor, regardless of the size of the pelvis, size of the fetus, dilatation of the cervix or station of the presenting part, who can foretell an unobstructed labor? Who can foretell minor, yet serious, abnormal constriction rings, extensions of the fetal head and other fetal disproportions?

Solution of posterior pituitary has a short, powerful contractive action on all smooth muscle. Patients in the preeclamptic states often show small petechial hemorrhages in the muscular coat of arterioles. Is it good mechanics to stimulate such an area with this solution when it is already insulted by disease? To me, this

Occasionally the first dose sensitizes the patient, and a future dose, however small, throws her into extreme shock. This can be very serious, but fortunately it is of rare occurrence.

A labor forced by solution of posterior pituitary may intensify the minor grades of abnormal cephalic presentation. This may place abnormal strains on the cervix, which in turn dilates unevenly and hence tears more easily and to a wider extent. With this increased portal of entry, would one not expect more minor grades of sepsis?

My opponents respond to these arguments by saying that they admit all of this theory, but they say that they are far too shrewd to be caught in these ways. They just use small doses cautiously, by which they gain a faster labor and no unusual abnormalities.

With these arguments in mind I present a study of 949 cases of administration of this solution during labor by my opponents, in which they tried to be "shrewd enough" by avoiding heavy doses injudiciously given. These cases are taken from St. Vincent's Hospital in Kansas City, which is visited by over 200 busy general practitioners who have maintained a maternal death rate of one in 265 deliveries with a variety of material closely approximating that published by the Chicago Lying-in Hospital over the same period.

Chart 1.—Total number of cases in which solution of posterior pituitary was used.

Chart 2.—Number of different physicians using this medicament. Notice how the many dropped to a few within the zone of influence. There must have been a reason for this change.

Chart 3.—Total number of dead babies during the years. Notice what a profound drop occurred and remained after the zone of influence.

drug given to patients with the toxemias of pregnancy is insult added to injury. It is contraindicated.

Solution of posterior pituitary intensifies uterine contractions. It increases intra-uterine pressure far above the usual. A careless steamboat engineer screws down his boiler safety valve to get more power and speed out of his ship. He sacrifices safety for speed. When one gives solution of posterior pituitary one increases the uterine boiler pressure far beyond the normal. Safety is sacrificed for speed in labor. When this increased boiler pressure places more stress on the fetus, is this safe for the newborn baby?

With increased intra-uterine pressure come increased uterine muscle contractions. These contractions must disturb the normal passage of food and gases across the uteroplacental barrier. Will the added insult of solution of posterior pituitary be safe for the baby?

Once this drug has been administered the resulting effect comes quickly, and the action cannot be as readily counteracted. After you pull the trigger, you cannot stop the discharge.

This record includes the years from 1922 to 1939. It is a history of physicians in private general practice. I know these physicians, they are shrewd, cautious and conscientious and were quick to catch the point which the following record clearly shows.

During these seventeen years 9,234 women were delivered; 1,713 had some sort of operative delivery, an operative incidence of 18.6 per cent; 949 received solution of posterior pituitary during early labor.

Chart 1 shows the total year by year of cases in which solution of posterior pituitary was used. During 1931 a complete study of the records was started, as designated by the left arrow. Within two years (right arrow) the completed study was presented before the Jackson County Medical Society. The space of time between these two arrows may be called the zone of influence which this study produced.

Something profoundly influenced these cautious physicians to discontinue the use of solution of posterior pituitary, as is shown by the marked drop in its use within the area of influence.

Table 1 shows the record of forceps and podalic versions in all the cases in which solution of posterior pituitary was used compared with the total operative

incidence for the whole hospital clientele. Regardless of the amount of solution each patient received, the various operative procedures show a much higher percentage among patients receiving solution of posterior

pituitary and/or quinine during early labor. The physicians who use solution of posterior pituitary and/or quinine used obstetric operations much more frequently.

Table 2 sets the total hospital incidence against the cases in which solution of posterior pituitary was employed in regard to manual delivery of the placenta, bag induction and cesarean section. These operative procedures were greatly increased in cases in which the solution was used.

Chart 4.—Operative incidence throughout the years. Notice how this incidence decreases after the zone of influence.

tion did not increase the incidence of shock or sepsis, that of hemorrhages was greatly reduced, while that of Bandl ring contractions was greatly increased.

Table 4 shows the average total first stages extending over a longer period than that observed with the 6,678 women delivered normally and without solution of posterior pituitary. The data show that labor in the

cases in which the drug was used was either slow and urged on by the drug or was delayed by the drug.

Infants in posterior positions, however, were delivered faster than those in similar positions in normal deliveries. The increased uterine power probably hastened dilatation, rotation and expulsion of the fetus.

Table 5 records maternal and fetal deaths. The cases in which solution of posterior pituitary was used are compared with the total hospital incidence. As my opponents argue, they were shrewd enough to prevent maternal deaths, but their fetal deaths were more numerous. This table shows what a deadly baby killer solution of posterior pituitary really can be.

Table 6 is a summary of the action of this drug which I presented to the Jackson County Medical Society in 1932. I believe that the influence of this summary produced a very fine improvement in the care

TABLE 6.—*Summary*

Maternal deaths unchanged
Operative deliveries two thirds more numerous but deaths unchanged
Temperatures not markedly increased
Baby death rate doubled at least, with or without quinine; stillbirths 2 to 6 times increased; hospital dead doubled; quinine as bad as solution of posterior pituitary
Labors 1½ to 2 times longer; posterior positions, shorter labor
High forceps and mid forceps deliveries at least doubled and low forceps deliveries increased
Versions doubled or more; manual dilation of cervix increased 10 times, retained placenta 10 times and Bandl's ring 2 times or more
Shock and/or hemorrhage not changed
Quinine as dangerous as solution of posterior pituitary

of obstetric patients in Kansas City, because, while the Kansas City birth rate dropped 1 per thousand in this area of influence, the maternal death rate decreased 4 per thousand live births; the stillbirth rate dropped 23 per cent; the incidence of cerebral hemorrhage

dropped 20 per cent, and that of birth injuries dropped 24 per cent and then began to increase again. During this time these fluctuations were far in excess of those observed in the state of Missouri or the United States in general.

With the exception of minor changes in the sizes of the multiples, the same summary holds true today.

SUMMARY

I have no right to state dogmatically that the use of solution of posterior pituitary during early labor will absolutely cause hidden damage in the pregnant woman or her newborn baby. I feel, however, that the conditions revealed by my study of a long record of cases in Kansas City, with the marked changes which occurred after I called attention to the use of this drug as a dangerous procedure, must by analogy be just as dangerous in any other city or county. I view with great concern the rising tendency in my own city of a venturesome group of physicians again to force labors with the patient under deep analgesia. I think I observe a mild increase in operative incidence, in stillbirths and in babies who die within one week after birth. These physicians have never displayed their wares publicly in statistical fashion, so their results are still problematic. From my own personal contact and study I feel thoroughly justified in repeating my first sentence: that I do not favor the use of solution of posterior pituitary during early labor.

THE USE OF SOLUTION OF POSTERIOR PITUITARY IN MODERN OBSTETRICS

JOSEPH B. DE LEE, M.D.

CHICAGO

Scientists sometimes have an uneasy feeling of doubt whether their epoch making discoveries are really benefiting mankind and try to argue themselves into the conviction that they are improving the social order. Fosdick of the Rockefeller Foundation asks "Can man control the forces he has let loose?"

Carrel says that our stature is not adjusted to the environment which we have created and sometimes what the sciences have given to man has fallen into unsafe hands. Labor saving inventions, he says, have dislocated employment, stunted our mental and physical growth, interfered with improvement of the species which naturally results from the struggle for existence, invited the development of political tyranny, increased the number and magnified the power of death dealing machines, and so on.

Whether or not these charges are borne out in our general social existence, we medical men must admit that sometimes as practitioners, let us say from over-enthusiasm or because we believe propaganda, we have been at fault in our application of the blessings of science—*anesthesia*, *asepsis*, *surgical technic*, *hospitalization* and *medication*.

Among these indictments solution of posterior pituitary has been singled out for this symposium. Rupture of the uterus, laceration of the cervix and dead babies follow in the train of its use all too often, yet it is being used more widely than ever.

Many preparations of solution of posterior pituitary are on the market, and although they are supposed to be standardized in Vögtlin units they vary not a little in strength and, what is equally important, some of them contain an appreciable amount of protein, which may cause anaphylaxis.

Further, combinations of solution of posterior pituitary with hormones and/or drugs—proprietary under fantastic names—have enjoyed worldwide recommendation and use. Manufacturers have been quick to realize the luciousness of a world market with more than 40,000,000 births annually, although many in the far countries are beyond the influence of seductive advertising.

It is claimed that these preparations are safer than straight solution of posterior pituitary, that they have virtues of their own which not only reduce the dangers of the oxytocic but also favorably influence labor; and obstetricians are importuned to administer these questionable drugs to all women for the purpose of hurrying delivery.

No convincing physiologic, experimental or clinical evidence has yet been presented to prove that thymophysin, pituthymin, thytuitary and the like are anything more than diluted solution of posterior pituitary or the drug in another guise (Nelson,¹ Greenhill,² Rucker,³ E. L. King,⁴ Muller and del Campo, Asher's laboratory in Berne).

It is significant that only one of these proprietary has been submitted to the Council on Pharmacy and Chemistry of the American Medical Association and that one was refused approval, its claims not having been substantiated.

Pharmaceutic firms advertise solution of posterior pituitary as an oxytocic for special indications but doctors the world over are using it so indiscriminately and the evils of such practice have become so notorious that it is time for the profession to take stock and see where it is going.

There is an increasing demand among American women for "streamlined labor," an unhealthy demand fostered by hysterical magazine and newspaper writers and, I regret to have to say, by not a small number of physicians. I have observed quite a number of their results, experienced many abnormally rapid labors, and learned that a streamlined labor can be as safe as a streamlined parachute.

What are the dangers resulting from injection of solution of posterior pituitary?

One thinks they all would come from the increase in the violence of the uterine contractions. Most of them do, but solution of posterior pituitary has other evil qualities. It can cause shock which, though seldom fatal, is often ominous and may leave permanent after-effects in the brain. Shock acts like asphyxia. Solution of posterior pituitary upsets the hormone balance in the body. Therefore its use should be avoided in cases of *dysthyroidism* and *diabetes*, *ergonovine* being used instead. In patients with heart disease it may be used only post partum, but here too ergot is better. In cases of threatened eclampsia it is claimed, though I have not

4. King, E. L.: Extensive personal communications to the author.

yet seen it, to cause convulsions. Indeed Schockaert⁵ reports postpartum eclampsia without premonitory symptoms with the use of solution of posterior pituitary. Here the pure oxytocic principle of the gland is recommended, and the reasons given are that the whole extract, containing the pressor factor, reduces the flow of urine, raises the blood pressure and also directly causes fits. The latest experiments (Bradbury) cause surprise by showing that the pressor factor affects the uterus and is oxytocic—like the true oxytocic factor—which leaves us about where we were before.

Perhaps we shall learn that solution of posterior pituitary causes other acute dys-hormonisms, which may explain death in labor, the convulsions and anaphylaxis.

Anaphylaxis is not so rare. It shows itself as severe urticaria, violent general or local pruritus, edema of the eyes, face, glottis or lungs, and in some cases as severe shock. A sizable literature is accumulating (McMann⁶ and others).

But the greatest dangers come out of the increase in the intensity and duration of the contractions of the uterus. These may reach a violence that will rupture the organ if the resistance to the advance of the projectile (the baby) is more than the strength of the wall of the exploding chamber (the uterus). How many cases of pituitary ruptures of the uterus occur will never be known. Either they are not reported at all or the women are buried—purposely without postmortem examinations—under another diagnosis. Many women should have the words solution of posterior pituitary put in their death certificates instead of postpartum hemorrhage, embolism, massive collapse of the lungs, anesthesia or shock.

McNeile⁷ in the early days of solution of posterior pituitary had no trouble in collecting sixteen cases of rupture of the uterus. Greenhill gathered twenty-three references from the literature (mostly older) giving thirty-eight cases (two from thymophysin, one from thyuitary); Dugger⁸ has unearthed three cases, possibly five, in Philadelphia, and all the men to whom I have written replied that they know of uterine ruptures from solution of posterior pituitary but cannot prove them, for reasons already stated. This year two ruptures occurred in Chicago hospitals, one from small doses of solution of posterior pituitary, doses usually considered safe.

I have seen pituitary blast the head through the cervix and the perineum, tearing both extensively, and if it happens when I give the drug it will happen when others give it, but I do not have to quote cases of evil results; the action of the oxytocic can be studied with a tokodynamometer, by looking at and feeling the uterus and by watching the effects on the baby. Of course we obstetricians are grateful to the physiologic research worker who has placed a scientific foundation under our clinical experience. Reynolds and Murphy have shown the actions of the uterus under the influence of solution of posterior pituitary, and those who really understand the mechanism of labor will need no admonition regarding the dangerous (for mother and

child) potentialities of the drug. Forces may be set in motion which cannot be controlled.

It has been claimed that combinations of solution of posterior pituitary can be formed which contract the fundus while they relax the lower uterine segment and cervix—but I could not find in this claim an iota of scientific proof. The more rapid dilatation of the cervix is due to the drug strengthening the contractions which force the head, with or without the bag of waters, through the parts, thus canalizing the cervix quicker. One does not have to know much of the mechanism of labor to understand how such violence will destroy the whole internal pelvic architecture which supports the pelvic organs in a manner so admirably adapted to bear the stresses, strains, torques and pressures of the natural functions for which they are intended. Even normal labor puts this well balanced muscular, fascial and connective tissue framework to a severe test. Action of solution of posterior pituitary is ruthless in destroying it and the portals are thrown wide open for the entry of infection. Theory and practice agree, so that statistical proof is not necessary.

I will quote from a letter from a former resident of the Chicago Lying-in Hospital newly located in a large town: "My work is progressing by leaps and bounds. There is a lot of chance for educating people to accept prenatal care and I can spend fifty years repairing the damage done by the injudicious use of pituitary to force stronger labor on the women in the community."

Solution of posterior pituitary can cause such violent labor pains, combined with powerful bearing down efforts, that the sudden overexertion causes cardiac death.

Uteri stimulated by solution of posterior pituitary not seldom suffer secondary atony with clot retention, thrombosis and embolism.

As for the babies, solution of posterior pituitary is of equal if not of greater danger. There is so much ignorance as to the baby's life processes in utero, and particularly during labor, that one is left with little but to theorize, which is especially true of the possible chemical and hormonal changes wrought in its system by the introduction of such a powerful drug. But one does not have to theorize about the physical effects of solution of posterior pituitary on the baby's health and life. Those can be seen during labor and at autopsy.

It is known that during a normal labor pain the baby is exposed to augmented pressure from all sides; its gross blood pressure is raised and also there are in its body local fluctuations of pressure which, as the cervix opens, are progressively greater in the direction of the vagina. This is because the resistance at the uterine outlet is diminished, and it is thus that the child is propelled into the external world. The baby's head naturally receives the brunt of the fluctuations in pressure, as is so plainly evident from the caput succedaneum and the minute hemorrhages in the scalp, the periosteum and often in the subjacent dura and brain. The physics of the process can be seen and understood every time one squeezes a tube of tooth paste.

The molding of the head is another result of the mechanical forces of the uterus, and its safety for the fetus is only partly guaranteed by the slowness of its execution. Every strongly molded fetal head should be scrutinized at postmortem examination. One will be astonished at the dislocation and deformation of the

bones, the distortion of the brain, the overstretched falx and tentorium, with even tiny dehiscences in them, and the minute and larger saggulations. Indeed, ruptures of the falx and/or tentorium are not so rare even in normal labor, and there is no doubt that these membranes occasionally tear and the child apparently recovers without threatening symptoms, i. e., while in the hospital.

As long as the bag of waters is intact the pressure exerted by the contracting uterus, which is known to be exerted equally in all directions, is counteracted by the resistance of the container walls, and the pressure in the baby's head is only slightly increased. As soon as the membranes rupture, a pressure flow in the direction of the head and of the cervix begins with each pain and grows greater as the cervix opens and the contractions wax stronger. It is these fluctuations of pressure which endanger the brain. With each contraction blood and lymph are driven into the brain, congesting the capillaries, weakening their walls and inviting edema. During the diastole of the uterus the blood and lymph ebb, but not completely. This is because of the increasing tonus of the uterus and the girdle of resistance. Each pain repeats the process with effects growing as the contractions become stronger until the gross picture described under molding is produced. Microscopically the cerebral changes are capillary dilatation and edema, blood points, diapedesis of leukocytes, serosanguineous exudation, edematous brain cells and, in bad cases destruction of these. The pathologic changes are like those of asphyxia. Indeed solution of posterior pituitary, by making long violent tetany of the uterus, causes asphyxia with slowing of the fetal heart, through stoppage of the uteroplacental circulation. When the membranes are broken the slowing of the fetal heart is in the carotid sinus mechanism—a heart block; the blood cannot get through the placenta. Confirmatory experimental evidence is brought by Woodbury, Hamilton and Torpin.

The "hypodermic manometer" was developed by them at the University of Georgia School of Medicine:

It has enabled us to measure the effective maternal blood pressure which supplies maternal blood to the placenta. We have recorded this effective pressure as well as the uterine pressure when pituitary preparations were given to three multiparous patients. Luckily no fatalities have occurred in these experimental studies.

Our results show that (1) intra-uterine asphyxia and (2) uterine tetany are real dangers associated with the use of pituitary preparations in the second stage of labor. In all three cases it reduced markedly the effective blood pressure to the placenta and produced incomplete uterine tetany which lasted from seven to twelve minutes. In one case intra-uterine asphyxia of the baby nearly occurred. The effective maternal placental blood pressure in this case averaged 85/50 mm. Hg between pains and 65/15 during pains. Pituitary extract reduced this to an average of 30/—10 mm. Hg for ten minutes and it stayed low throughout the remainder of labor. At one time this effective pressure was reduced to 5/—25 mm. Hg (5 systolic and 25 mm. Hg below zero diastolic pressure). This meant that the uterus was so contracted that maternal arterial blood not only could not enter the placenta, but that the uterus was actually squeezing blood from the placenta into the mother's aorta as well as into the veins. The maternal blood supply to the placenta was stopped. The baby's heart sounds became slow and faint and at one time we were not sure that we could hear them. Fortunately the uterine tetany subsided somewhat, the effective placental pressure gradually increased to nearly normal and the child's heart sounds became louder and regular.

What chemical changes go on in the brain, in the endocrine glands and in the fetal body are not known, but there is enough other information to make one realize that the brain is a very tender organ, that it bears the insults of the forces of labor poorly, and therefore that one should not augment the intensity of these forces without very good reason.

On the contrary, understanding and fearing their power one should rather reduce the forces to the minimum required for the delivery of the child.

In this connection a recommendation by Dr. Rawlins⁹ of London 150 years ago is of interest. He forbade bearing down in the second stage of labor, insisting that the baby be born by the uterine action alone. He claimed that there were less perineal lacerations and fewer dead babies with this practice. A modern delivery room without "Bear down! Bear down!! Bear down!!!" would be quite a curiosity.

The harmful action of solution of posterior pituitary in normal labor is thus clear. Solution of posterior pituitary (1) strengthens the uterine power and prolongs its action, (2) shortens the diastolic rest periods and (3) increases the intra-uterine tension by raising the tonus of the muscle—in short, solution of posterior pituitary makes normal pains pathologic and exaggerates all their evil effects on both mother and baby.

A totally neglected aspect of the use of solution of posterior pituitary to hurry normal labor is the medico-legal one, but it was brought to my attention recently in a poignant manner: A father brought his spastic and idiotic 6 year old son to me, asking me to appear as expert witness in an action he proposed to bring against his doctor. The doctor had given solution of posterior pituitary to start and then to expedite labor so that he could go on his vacation. The labor was tumultuous, painful and spontaneous and the child suffered a cerebral hemorrhage, diagnosed by four of the city's leading pediatricians and neurologists as birth injury. I had much trouble in saving the doctor from a lawsuit.

Inquiry of the Bureau of Legal Medicine and Legislation of the American Medical Association brought this reply from Dr. W. C. Woodward, condensed from a long exhaustive opinion:

As far as civil liability is concerned, the question would have to be decided by the testimony of experts in the community testifying as to whether such practice in the individual case represented "due diligence, ordinary knowledge and skill and best judgment":

"To the foregoing may be added the statement that no professional standard anywhere or at any time could justify a physician in doing anything that would jeopardize the life and well being of mother or infant solely for the physician's convenience. Moreover, consent by the father or mother, even with a thorough understanding of the matter, would not excuse a physician who deliberately induces and expedites labor solely for his own convenience, to the material danger of the mother and child." Further, it would be necessary to prove cause and effect.

The use of solution of posterior pituitary or other agency to induce labor may or may not come into the field of criminal practice, depending on the laws of the states. Herzog says that the legal term abortion or miscarriage applies from the day of conception "to the

9. Rawlins, R. A.: A Dissertation on the Structure of Obstetric Forceps, London, B. & J. White, 1793.

time when a full term labor commences." Many states insist that induced abortion is punishable by imprisonment for from one to ten years and that if the mother dies from the operation the person procuring or causing the abortion or miscarriage shall be guilty of murder.

Again Dr. Woodward stated:

If then, as seems to be indicated by the definitions set forth above, an abortion covers all premature deliveries of ovum, embryo and fetus up to the termination of natural gestation, it may be questioned whether a physician can lawfully do anything to expedite the onset of labor, unless it is necessary to do so for the life—and in some states possibly for the health—of mother or baby. If the induction of premature labor for purposes of mere convenience is unlawful, the consent of the mother and of her husband would not protect the offending physician from criminal prosecution. How far such consent would go toward relieving the offending physician of civil liability or of mitigating damages is another question, involving the rather difficult problem of the extent to which a child, injured in the process of birth, may have a right of action against the physician who is responsible for the injury, notwithstanding anything that the parents may have authorized to be done in the conduct of labor.

However, solution of posterior pituitary is one of the great blessings that science has conferred on women, and the profession is now well agreed on its scientific indications.

SCIENTIFIC INDICATIONS

During Pregnancy.—Hofbauer¹⁰ and I simultaneously discovered that solution of posterior pituitary could cause the relaxed ureter to expel its contents and thus aid in the cure of pyelitis. I have used it only after delivery but Hofbauer claims that it is safe during early pregnancy because the uterus has not yet become sensitized.

In case of abortion in progress, after an appendix operation, solution of posterior pituitary may be exhibited for the double purpose of emptying the uterus and overcoming ileus.

In septic abortion after a preliminary course of quinine, 3 grains (0.2 Gm.) each hour for five doses, 5 Vögtlin units is given hourly until the ampule is used up. Solution of posterior pituitary is also usable in all abortions actually in progress to hasten the process and save blood. Further, when curettage is done for incomplete abortion one half ampule, injected deep into the cervical wall, will stiffen the uterus, separate the secundines and give the curet a harder and safer surface to work on; it will also reduce the loss of blood. The blood should always be saved.

Labor.—It is safe to induce labor with solution of posterior pituitary but only if proper precautions are observed. It is never to be used in cases of placenta praevia. I found that Hofbauer's nasal method was dangerous, and I learned too that some women react to even small doses of the oxytocic with too strong pains no matter how it is given. (Reynolds showed this in his tracings.) I have seen 3 minims (0.2 cc.), or 2 Vögtlin units, put both mother and baby in peril. Therefore to induce labor I give one half unit with a tuberculin syringe and, with ether can in hand, watch the effect. At the end of twenty minutes 1 unit is given, and thereafter a like dose every twenty to thirty minutes until some effect is seen. Then I wait a while and if the force of the contractions dies off I repeat the dosage

or increase it a little, not using more than one ampule. 10 Vögtlin units, in one trial. I have discontinued the use of quinine to sensitize the uterus because it is inefficient and occasionally harmful. The morning of the induction, the patient is given castor oil. In cases of high blood pressure some recommend pitocin, which is supposed to have the blood pressure raising element of solution of posterior pituitary removed. In my own experience, this has not been the case and now, since Gardiner and Bradbury¹¹ have shown that pitressin, which was thought to be free from oxytocic action, has as much as pitocin, the possible pressor action of pitocin is to be considered.

During Labor Itself: As has been sufficiently emphasized and proved, there is no justification for the use of any oxytocic in normal labor. Expediency and convenience of the doctor or patient are not scientific indications and, outside of running the risk of being legally held responsible in the event of accidents, the medical conscience forbids such use. No one has demonstrated any prophylactic virtues for solution of posterior pituitary for either the mother or the baby in normal labor.

In cases of atonia uteri, pure primary uterine inertia in the absence of a contracted pelvis, fibroids or mechanical organic obstruction, I make a brief trial of solution of posterior pituitary, watching and feeling my way carefully, like handling dynamite. These precautions are especially necessary after the membranes have ruptured.

For atony during the second stage of labor, even greater caution is necessary, although it is here that the practitioner often uses the least. I feel sure that the forceps operation with episiotomy is safer to terminate labor, after complete dilatation, with the head on the perineum, than giving a woman a shot in the arm to blast the baby out of her person. Every man who practices obstetrics ought to know how to do an episiotomy and the prophylactic forceps operation. The baby's brain will suffer less damage and the mother's pelvic organ supports will likewise be safer.

In cases of abruptio placentae it is permissible to give solution of posterior pituitary—again with precautions—to hurry labor and increase uterine tonus, but never in placenta praevia until the baby is delivered.

The Third Stage of Labor.—Should solution of posterior pituitary be used as a routine in the third stage of labor? Such practice is widespread but the reports of the results are conflicting (Williams,¹² Percival,¹³ Clayton,¹⁴ Fortin¹⁵ [2,200 cases]). Some state that it shortens the third stage, reduces loss of blood, favors the expulsion of the placenta, prevents postpartum hemorrhage and favors involution, which minimizes the risks of infection. Others deny these actions. In my experience solution of posterior pituitary does reduce the duration of placental delivery and the loss of blood but not much, and further I have had not a few pla-

central incarcerations which wiped out much of the pleasure of the other two advantages.

Some, as soon as the shoulders have passed the vulva, give an ampule of solution of posterior pituitary intramuscularly; others at the same time give 2 units intravenously; some wait till the feet have left the introitus and then inject the drug; others insist that the placenta must be out before any oxytocic is allowable.

For many years, in all operative deliveries under a general anesthetic, we gave an ampule of solution of posterior pituitary immediately after the child was born and we recommended the procedure. In spontaneous deliveries in which the uterus acted well, we did not use the drug as a routine but gave it when the patient had had much obstetric analgesia and/or anesthesia. With local anesthesia it was not needed.

At present at the Chicago Lying-in Hospital we are experimenting with ergonovine intravenously, injected as a routine when both shoulders have appeared, and we find that it is not to be recommended for general practice. It is useful, like solution of posterior pituitary, after operative delivery and when atonia uteri is feared.

For postpartum hemorrhage solution of posterior pituitary is invaluable, though it fails occasionally. Of course it will not stop bleeding from a laceration or from a ruptured uterus (which incidentally it may have caused) but it will almost always cause a uterus to contract powerfully, especially if administered intravenously or injected directly into the uterine muscle. I always use ergonovine to back up the action of solution of posterior pituitary. Sometimes it is better than solution of posterior pituitary, particularly if put into a vein.

In the Puerperium.—Solution of posterior pituitary has yielded place to ergonovine in nearly all cases in which an oxytocic is needed during the puerperium. I can imagine that it might be used to expel a piece of placenta or a clot that remains in the uterus, or in late hemorrhages of a hormone nature, together with ergonovine.

SUMMARY

1. Proprietarys such as thymophysin, thyuitary, pituthymin and combinations with quinine are not to be recommended. They are diluted solution of posterior pituitary or are the drug disguised.

2. Even natural labor can cause damage and/or death to both mother and baby.

3. Solution of posterior pituitary augments the forces of labor which inflict such damage and/or death—lacerations of the cervix, vagina, perineum, even rupture of the uterus, and cerebral damage in the babies.

4. Solution of posterior pituitary may cause severe shock and anaphylaxis and may explain certain fatalities in dyshormonisms and circulatory and renal diseases.

5. The medicolegal aspects of administering a potent and dangerous drug, as a matter of convenience, are worth consideration.

6. Proper indications for solution of posterior pituitary are numerous: in pregnancy to induce labor, in labor, and post partum. These indications are well defined and defensible.

CONCLUSION

Solution of posterior pituitary is one of the great boons that science has conferred on women, but it should not be used without a clear, generally accredited, scientific indication. It is now being supplanted by ergonovine in many places.

5028 Ellis Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. SHARKEY, PENDLETON AND DELEE

DR. RICHARD TORPIN, Augusta, Ga.: The papers presented have forcefully described the abuses and misuses of solution of posterior pituitary. We are convinced from studies at the University of Georgia (see Woodbury, Hamilton and Torpin) that it may be hazardous to use solution of posterior pituitary prior to delivery of any patient in labor irrespective of the strength of the pain. We found that 1 minim (0.06 cc.) of solution of posterior pituitary administered intravenously caused a marked increase in the strength of uterine contractions, more frequent contractions and even tetany, and reduction of maternal blood flow to the placenta over a pathologic period of time. Solution of posterior pituitary increased the uterine contraction pressure from values of 25 to 45 mm. of mercury to values of 80 or 90 mm. Patients who had weak pains have the larger increases and are, as far as we know, just as likely to have uterine rupture as any patient. In all cases solution of posterior pituitary placed abnormal stresses on the uterus. Concerning the character of the contractions, the normal rest period between pain is reduced or abolished. Incomplete tetanus was always observed and in one of the five patients complete tetanus was present for six minutes. Normal contractions did not recur until ten minutes after administration of 1 minim of solution of posterior pituitary. With these more or less continuous pains the patient bears down and the abdominal muscles are used to hasten delivery, additionally increasing the pressure and possibly causing further damage to the baby and to the birth passages. Concerning the reduced maternal blood flow to the placenta, much reduction occurs during a normal labor contraction but it is of so short duration that it produces no significant fetal anoxemia. Solution of posterior pituitary, however, not only increases this pressure but prolongs the period of elevated intra-uterine pressure, resulting in fetal anoxia of pathologic duration. In one case the intra-uterine pressure was so great that the uterus at times was actually squeezing maternal blood back into the aorta as well as into the veins. The pressure remained high so long that the maternal blood supply to the placenta was markedly curtailed over ten minutes. The baby's heart sounds became slow and faint and finally could no longer be heard. Fortunately the uterine tetany subsided so that the placenta circulation gradually increased and the fetal heart sounds again became audible. We have in our records graphic proof of the factors which may account for the dangers of solution of posterior pituitary: uterine rupture, injury to birth passages and fetal anoxemia, with attendant injury to the nerve cells or blood vessels within the brain.

DR. ALBERT B. DAVIS, Camden, N. J.: With the Philadelphia Committee on Maternal Welfare Dr. Sharkey condemns solution of posterior pituitary for the death of twelve infants in 1,000 stillbirths and as the cause of four out of ninety cases of ruptured uterus. He points out its dangers to mother and child. In all of Dr. Sharkey's conclusions I can agree. There is no doubt of the contraindications to, and the dangers in, its use in normal and in obstructed labor. The question is When, if ever, can solution of posterior pituitary be used to definite advantage in the first or second stage of labor? This indication limits its use to a comparatively small number of cases of primary inertia. Even these cases, in my own experience, have been more frequently treated by sedation and supportive measures until dilatation, and then instrumental help. Dr. Sharkey apparently found solution of posterior pituitary indicated in only eighteen such out of more than 10,000 cases in his hospital services, an incidence of one in 570. Yet these are the cases in which the judicious use of solution of pituitary may be helpful. In all forms of inertia the contractions are weak, but the tone may vary, being normal or normotensive, low or hypotensive or high or hypertensive. I have made some tracings which are schematic. In normal labor the uterine contractions are more or less regular and of what is called normal strength. In inertia the tension may be about the same, or may be low or may be high, but the waves are always small. The arrows in the center indicate the giving of a small dose of solution of posterior pituitary.

In normal labor the contractions are increased intensely. In normotensive inertia the contractions are increased and the tone somewhat. In hypotensive inertia both contractions and tone are increased. But in hypertensive inertia the contractions are practically destroyed by the increase in tone. There is already a high tension of the uterus, and solution of pituitary given in that condition does harm instead of good. The normotensive and hypotensive inertias are helped by solution of posterior pituitary, which always means properly given in small initial doses, but in the hypertensive cases it is not only useless but dangerous. In any case the dose should begin with 1 to 1½ minims and not exceed 3 minims at thirty-minute intervals. If we cannot differentiate our cases, we should probably do better not to use solution of posterior pituitary at all in the first or second stage of labor.

DR. JAMES K. QUIGLEY, Rochester, N. Y.: In 1915 I wrote a paper on solution of posterior pituitary in obstetrics which was published in *THE JOURNAL*. This was only a few years after Blair Bell's pioneer paper. The enthusiasm which greeted the advent of this new agent is reflected in the opening paragraph of my paper, "Throw away your forceps and use pituitrin" is the glowing headline of a recent advertisement of a large pharmaceutical concern." This report was based on the use of solution of posterior pituitary for inertia in the second stage of labor. The early popularity has given way to a conservative attitude, for soon cases of uterine rupture following the use of this powerful oxytocic appeared in the literature. I was surprised that solution of posterior pituitary during labor would be the subject for discussion on this program, for I have not seen the drug used during the first or second stage of labor for at least ten years. The indications laid down by me in 1915, considering the popularity of solution of posterior pituitary, expressed a guarded attitude. They were a fully dilated cervix, a normal presentation and position, an engaged head, the absence of disproportion and the presence of inertia. In addition to these indications the following injunction was made: "Pituitary extract must be used judiciously and with a due appreciation of the possible dangers of so powerful a uterine stimulant. This is the most important point." Today I believe that outlet forceps is safer than the employment of a powerful oxytocic with susceptibility of the uterine muscle an unknown factor. This would seem like a retraction. It is. We live and learn, and we are inclined to become more conservative. Dr. Pendleton has shown conclusively the dangers of solution of posterior pituitary to both mother and child. He has also shown a lower fetal mortality and lower maternal morbidity following its abandonment, and, granted that the incidence of serious complications such as fetal asphyxia, contraction ring dystocia or ruptured uterus were only one in 100 cases of its use, that is too high a price to pay when other measures may be employed with greater safety. The safe rule is no solution of posterior pituitary during the first and second stages of labor.

DR. E. D. PLASS, Iowa City: I appreciate this opportunity to discuss Dr. DeLee's communication. I am in almost complete agreement with his observations and conclusions. We have occasionally differed widely, but now we find a common ground in condemning the indiscriminate use of solution of posterior pituitary. It is a valuable therapeutic agent if employed properly but is dangerous when used during the first and second stages of labor. Solution of posterior pituitary is especially misused by the general practitioner and more commonly during home deliveries, when facilities for treating the ensuing difficulties are largely nonexistent. An analysis of the records of 1,000 home deliveries by general practitioners in Iowa reveals that solution of posterior pituitary was used "to strengthen labor pains" in 325 cases, or 32.5 per cent. In 90 per cent of the cases, "pituitrin" was employed and the dose varied from 1 minim to 1 cc., while in the remaining patients one of the thymus-pituitary atrocities was used. The admitted stillbirth and neonatal death rate in this group was 2.8 per cent as against 2.5 per cent among the 675 patients who were not subjected to such therapy. It is doubtful whether this small difference is signifi-

cant. The single maternal death in the series was of a patient who had been given solution of posterior pituitary but who allegedly died from pneumonia on the second day after delivery. From the philosophic angle the argument against the use of solution of posterior pituitary during labor is difficult to answer. It is a well accepted principle that treatment should be directed at the relief of some condition existing in the patient; even placebos have this virtue. The employment of solution of posterior pituitary during labor contravenes this principle, since there is no evidence that a rapid, pituitary stimulated delivery is better for the mother or the baby; in fact, the weight of experience strongly supports the idea that a slower, more natural parturition is better and safer. Obviously, then, the effect of the medication serves only the convenience of the physician, and it can be expected to do him no harm irrespective of the dose or the circumstance. Those who have employed it critically since it was introduced twenty-five years ago will generally subscribe to the restrictions Dr. De Lee places on its use. It has no place in the conduct of the first stage of labor except in rare and carefully selected cases, and in the second stage forceps is safer and better. I have seen perhaps half a dozen patients with uteri ruptured by the action of solution of posterior pituitary and have had histories, from patients and physicians, of some dozens of babies who have died following and probably because of, administration of the preparation. Even in the induction of labor it is not completely safe.

DR. E. L. KING, New Orleans: I might paraphrase Mark Anthony's remark. It seems we have come here to bury pituitary, not to praise it. That is proper in the majority of instances. The argument appears to be strong that in labor there is practically no indication for solution of posterior pituitary. We may say that in primary inertia it would appear occasionally that it might be necessary to use some uterine stimulant. In the vast majority of instances that can be avoided simply by taking time. A woman with slow, irregular pains for two or three days can be supported and can be strengthened and can be rested. The difficulty in such a case comes particularly with the practitioner and more especially with the rural practitioner. We have to bear him in mind, and that is especially true in the South, where he has a large territory to cover and where his time is limited. Under such circumstances we may admit that a very small dose of solution of posterior pituitary, carefully watched, might be prescribed. I feel that one should never use more than from one half to 1 minim and that it should not be repeated if there is any untoward result. The effects on the uterus and on the fetus should be watched very carefully. Unfortunately, some manufacturers are advocating thymus combinations with the explanation that they are perfectly safe. I do not think that we can say they are; the pituitary content is there and I do not feel that the thymus extract modifies the pituitary action to any extent. The moral is preferably not to use pituitary at all in the first and second stages of labor. In the New Orleans Charity Hospital we deliver over 4,000 women a year, and the pituitary cases a year can be counted on the fingers of the hand. We have more worry and discussion over whether we should use pituitary than we have over whether we should or should not perform a cesarean section. We have an ironclad rule that pituitary is not to be used except when specifically ordered by a senior member of the house staff or a member of the visiting staff, before the third stage of labor. We feel that such teaching is better than any other form of teaching and that the health of the mother and the health of the baby will be better safeguarded by refraining from its use except under very definite indications.

DR. DOUGLAS P. MURPHY, Philadelphia: Dr. Sharkey condemns the use of solution of posterior pituitary for the purpose of shortening normal labor. He advocates its employment in the treatment of primary inertia but insists on small dosage. I agree with him. The danger which results from the improper use of solution of posterior pituitary is more a problem of dosage than a question of which patient should receive it, and for that reason I think that those who oppose its use have missed the point entirely. They have condemned the use of the

drug when in practically every case I am quite certain that doses were used far in excess of what should have been employed. I have recorded in more than 100 cases, with the Lorand toco-graph, the character of the uterine movements initiated by the hypodermic administration of solution of posterior pituitary at term and during labor. These observations show that optimal doses either initiate or reinforce rhythmic uterine contractions, whereas overdosage almost invariably induces tetanic spasm. The latter may last for many minutes before good quality rhythmic contractions begin. At our hospital recently a patient was ordered 1 minim (0.06 cc.) of pitocin; by mistake she received 1 cc. She experienced a uterine spasm which lasted thirty-three minutes. We have found that, if tetanic spasm is to be avoided, the optimal dose is in the neighborhood of 1 minim. Such a dose is effective for about thirty minutes and can be repeated safely at that interval as often as indicated by the condition of the patient. For accuracy in dosage we have found most suitable a 0.25 cc. syringe. With this, one is not so likely to give an overdose as when employing the usual 1 cc. tuberculin syringe or the 2 cc. syringe. Solution of posterior pituitary has a place in the treatment of certain patients in labor, but only when a nontetantizing dose is employed, and that dose is in the neighborhood of 1 or 2 minims. I take issue with the gentlemen who condemn the use of solution of posterior pituitary because I am certain that they are condemning it where patients have received excessive doses of the extract and not optimal ones. We rarely see a tetanic spasm following a dose of 1 minim or less of solution of posterior pituitary or pitocin. I do not think that solution of posterior pituitary should be condemned but that the dose should be in the neighborhood of 1 or 2 minims. If a good result follows 1 minim, the result will be no better with 2 minims. In fact, an excellent result may follow with one half minim.

DR. J. I. HOFBAUER, Cincinnati: If we listen to the arguments against solution of posterior pituitary it seems that I owe you an apology for having introduced into obstetrics its use during labor. If you will look up my paper published in the September 1938 issue of the *American Journal of Obstetrics and Gynecology* you will find the indications and contraindications which have been stressed by Dr. De Lee pretty similar to my views. The introduction of solution of posterior pituitary more than twenty-five years ago, as a means of initiating and reinforcing labor pains, constitutes a landmark in the development of the science and art of obstetrics.

DR. RUDOLPH W. HOLMES, University, Va.: Through my contacts with the personnel of a large pharmaceutical house I was given a supply of solution of posterior pituitary before the product was publicized and I used it in numbers of cases. Years later, when visiting the plant, I was shown a narrow test tube about a third full with a reddish black crystalline substance. The statement was made that, as far as their chemists were able to determine, the contents of the tube were the ultimate active secretory substance of the postpituitary gland; as there never has been a public avowal thereon we may be certain that there never was a conclusive verification of the opinion. The startling thing is that it was stated that one millionth of a grain of that crystalline substance had a potency equivalent to 10 cc. of the extract. I cite this matter to accentuate the direful consequence which may ensue if this powerful drug is administered to a parturient woman who is peculiarly susceptible to the effects of the medication. In the early days when full doses were indiscriminately given to stimulate contractions I collected some thirteen reports of ruptured uteri with death in about eighteen months in the city of Chicago. I was invited to discuss the use and abuse of postpituitary extracts before a county medical society in an adjacent state: I fervidly stressed the risks which might result from massive dosages. Some weeks later the secretary wrote me that one of my auditors had been called to a woman early in labor; in some four to six recurrent visits he gave her an ampule of this powerful drug. At his last visit he found a woman dead from a ruptured uterus. The postpituitary products are among the greatest gifts to the welfare of the

obstetric women, but the abuse of the administration makes it a menace in the hands of the unwary. It should be given with extreme circumspection, and always in minimal doses—before the birth of the child. I believe that nasal administration is the safest method of administration: absorption is slow; with the first sign of undue response to the drug the nasal pack may be removed: when given parenterally the dosage is beyond recall.

DR. SAMUEL R. M. REYNOLDS, Brooklyn: I knew that Dr. Torpin was going to be good enough to present the work of his clinic, which shows that during a large portion of the contraction of the uterus in labor intra-uterine pressure exceeds the effective arterial pressure in the maternal placenta. That means that there is no flow of blood through the maternal vessels of the uterus during this part of the normal labor contraction. For this reason it is worse to induce a spasm in which this effect is sustained for a time. I might point out that mechanisms exist which protect the baby for the intermittent contraction but not for the spasm type of contraction. The difference in chemical composition between the maternal blood and fetal blood is such that toward the end of pregnancy there is a high degree of unsaturation of the maternal blood; the venous blood from the uterus (in rabbits) comes back from the uterus with about 25 per cent oxygen saturation, whereas earlier in pregnancy it may be as much as from 60 to 80 per cent. The fetal blood, on the other hand, through buffering systems, and differences in hemoglobin type, is able to take up from maternal blood, held in the placenta, an increasing amount of oxygen. Obviously this can take place for only a short time.

DR. GEORGE F. PENDLETON, Kansas City, Mo.: This discussion seems to come down more or less to and center around inertia. I will admit there is such a thing as uterine inertia, but when a woman goes into labor and then labor pains stop, that is not inertia. There is something that causes that, and you had better give that woman some food and rest and she will come along.

DR. JOSEPH B. DE LEE, Chicago: It seems that most of those who have discussed these papers have missed the point. I hardly think any one of our authors doubts that there is good use for solution of posterior pituitary. I know that I have emphasized that clearly, but the point that I wanted to bring out was that there is no use for solution of posterior pituitary in normal labor. Now why should you want to hurry a normal labor? The woman certainly has plenty of time, and if she takes nine months producing a baby I don't think she could spend her time in any better way than in devoting a few hours to delivering it. From the woman's point of view there is no hurry. Nobody has ever proved that solution of posterior pituitary has any prophylactic values. Dr. King mentioned that the country doctor with little time wants to get the baby out and go home. But there should be no hurry. Let that country doctor go away and come back, even though it is some distance, timing his visits, and if he finds the baby in bed it probably won't hurt very much. I wanted in my paper to make a plea for the safety of the cervix, the pelvic floor and the supports of the uterus. And I wanted to make a plea for the baby's life, immediately, and for the integrity of its brain in the future.

No Efforts Too Great.—As the science of medicine has developed, it has come more and more to dominate the practice of medicine, to standardize procedures, to improve the diagnosis of disease, to rationalize its treatment, and to demonstrate methods of preventing disease. In the cultivation of science, leaders of medicine have concentrated their thought and effort on the biological, chemical, and physical sciences as applied to the study of human life, striving to understand more deeply the laws and principles by which it is preserved and the ways and means by which it is disturbed. The rapid progress of medical science has brought untold benefits to the human race and as a mark of human progress the history of medicine during the last century stands supreme. No efforts are too great to maintain and accelerate its growth.—Robinson, G. Canby: *The Patient as a Person*, New York, Commonwealth Fund, 1939.

TOBACCO AND CORONARY DISEASE

JOHN P. ENGLISH, M.D.
Fellow in Medicine, the Mayo Foundation
FREDRICK A. WILLIUS, M.D.

AND

JOSEPH BERKSON, M.D.

ROCHESTER, MINN.

During recent years the medical profession has displayed increasing interest in the problem of tobacco smoking and its influence on persons who are in good health as well as on patients afflicted with disease.¹ Numerous laboratory studies have been conducted in which the effects of tobacco smoke on normal animals have been investigated.² These investigations have been important but have cast little light on the problem as it affects human beings owing to the fact that great differences exist between conditions of normal animals ordinarily unexposed to tobacco smoke and the varying states of human beings, who as a species have been exposed to this agent for many generations.

Pearl's study of human longevity in relationship to the smoking of tobacco has been an important contribution to the subject.³ His study indicated that the expectation of life of nonsmokers exceeded that of smokers and that among smokers average longevity decreased progressively with increasing degree of smoking. Several clinical studies that have dealt with the effects of smoking on coronary disease have been published but the conclusions drawn have been comparatively indefinite.⁴

In undertaking this study we were clearly aware of the fact that we were pursuing only one of the many considerations that enter into the problem of coronary disease. In fact, we presumed that in all probability the smoking of tobacco was not an etiologic factor but was perhaps an influence that affected the course and the progress of the disease. In an investigation dealing with the effect of a chemical agent in a large number of individuals one must be aware of the wide range of reactions that undoubtedly exists and which may greatly influence the conclusions of any study, experimental, clinical or statistical. We have carefully considered various approaches to the problem and have concluded that at the present time the most satisfactory method of study available to us would be a statistical survey of a representative series with proper controls. The more

thorough method of actually conducting clinical experiments on a selected group of individuals would require many years to complete even if it was practicable.

MATERIAL

This study was initiated by selecting from our files 1,000 records of representative cases of well established coronary disease. They comprised cases of recurrent angina pectoris, healed cardiac infarction and recent and acute cardiac infarction. It soon became apparent that certain modifications in this sampling were desirable for statistical reasons, owing to the extremely small number of females and the small number of both sexes less than 40 years of age which are to be found in a random series of 1,000 patients with coronary disease. It was therefore determined to include only males 40 years of age or older and the cases were grouped for the following age periods: 40 to 49 years, 50 to 59 years and 60 years and more. The requisite number of males to complete a total series of 1,000 cases was then secured from our records, selected only on the basis of age and cardiac status, so that they should accord in other respects with our basic requirements of randomness of selection. Then for each case it was noted whether the individual was or was not a smoker and, if a smoker, the degree of smoking was graded (on the basis of 1 to 4, in which 1 indicated least and 4 most smoking) as accurately as possible. The great majority of individuals in this study who were smokers used cigarettes, whereas only a small fraction of cigar smokers and pipe smokers was present.

Then we secured for a control group of individuals without coronary disease the histories of 1,000 males taken consecutively from our files for the same years as the series of cases of coronary disease. Only age and sex and the nonexistence of coronary disease were consulted in this selection; no attention was paid to the individual's status as a smoker. This, in fact, was not obtained from the record until later. The individuals taken as controls comprised patients whose examinations were recorded as revealing normal conditions or abnormalities entirely unrelated to the cardiovascular system. Here, as for the group with coronary disease, data regarding smoking and its degree were recorded.

The results of the analysis of these two groups are found in table 1. Among the group of patients with coronary disease, 698 (69.8 per cent) were smokers, whereas in the group of individuals without coronary disease there were 663 (66.3 per cent) persons who smoked. This represents an increase of only 3.5 ± 2.1 per cent of smokers among the patients who had coronary disease. However, when the analysis is carried further and the incidence of smokers in the various age groups is investigated, some marked differences become apparent. The incidence of smokers among 187 patients with coronary disease between the ages of 40 and 49 years was 149 (79.7 per cent) as contrasted with 187 smokers (61.9 per cent) among 302 in the group without coronary disease. This represents a difference of 17.8 ± 4 per cent,⁵ which is statistically

5. The figure after the sign \pm is the "standard error of the difference." If the difference is as large as twice the standard error it is generally considered "statistically significant" because only in five times out of 100 would so large a difference between the groups considered be expected to occur as a matter of chance, when there really was no difference. However, this applies to the general case of a difference in either direction, that is, for instance, here, regardless of whether incidence of smoking was greater or less in the group with coronary disease. Since here we actually consider as relevant only differences in one direction, that is, when the smokers are of greater frequency in the group with coronary disease, the equivalent rule is that a difference which is as large as 1.6 times its standard error is "significant." Such a difference in the relevant direction will occur by chance only five times in 100 when, in fact, there is no difference. In this instance the difference is more than four times its standard error.

significant. Comparison of the remaining age groups reveals no significant differences.

We then selected the consecutive records of 1,000 males 40 years of age and older on the basis of tobacco smoking only, recorded the degree of smoking, and determined the incidence of coronary disease among

TABLE 1.—Comparison of Incidence of Smokers in a Group of Males More Than 40 Years of Age Who Had Coronary Sclerosis with the Incidence in a Control Group of Similar Males Without Coronary Sclerosis

Age, Years	Coronary Sclerosis			Control: No Coronary Sclerosis			Difference Coronary Sclerosis Minus Control, per Cent	P *
	Total	Smokers		Total	Smokers			
		Num- ber	Per Cent		Num- ber	Per Cent		
40 to 49	187	149	79.7	302	187	61.9	+17.8	<0.001
50 to 59	382	274	71.7	371	274	73.9	- 2.2	
60 plus	431	275	63.8	327	202	61.8	+ 2.0	0.28
Total	1,000	698	69.8	1,000	663	66.3	+ 3.5	0.05

* The probability that as large a difference in the direction found would occur by chance in random samples, if actually there was no difference. The difference is considered "statistically significant" if the P is 0.05 or less. The P is given only when the difference is positive.

them. As a control to this group, 1,000 males 40 years of age and older were selected on the basis that they were not smokers and in this group the incidence of coronary disease was likewise obtained. Table 2 reveals the results of the analysis for these two groups. There were fifty-four instances (5.4 per cent) of coronary disease among the smokers in contrast with thirty-eight (3.8 per cent) among the nonsmokers. The difference is 1.6 ± 0.9 per cent, which is barely significant statistically.

However, when these two groups were subdivided into specific age groups the differences in the incidence of coronary disease among the smokers and the nonsmokers were more impressive. The incidence of coronary disease among smokers between the ages of 40 and 49 years was 4.8 per cent as contrasted with only

TABLE 2.—Comparison of Incidence of Coronary Disease in a Group of Male Smokers More Than Forty Years of Age with the Incidence in a Similar Group of Nonsmokers

Age, Years	Smokers			Control Nonsmokers			Difference Smokers Minus Control, per Cent	P *
	Total	Coronary Disease		Total	Coronary Disease			
		Num- ber	Per Cent		Num- ber	Per Cent		
40 to 49	208	10	4.8	208	2	1.0	+3.8	0.01
50 to 59	388	24	6.2	388	10	2.6	+3.6	0.01
60 plus	404	20	5.0	404	26	6.4	-1.4	
Total	1,000	54	5.4	1,000	38	3.8	+1.6	0.04

* The probability that as large a difference in the direction found would occur by chance in random samples, if actually there was no difference. The difference is considered "statistically significant" if the P is 0.05 or less. The P is given only when the difference is positive.

1.0 per cent in the same age group among the nonsmokers, revealing a difference of 3.8 ± 1.6 per cent, which is statistically significant. A similar situation prevailed in the age group of 50 to 59 years, in which the incidence of coronary disease among smokers was 6.2 per cent and among the nonsmokers was 2.6 per cent, indicating a difference of 3.6 ± 1.6 per cent, which is again statistically significant. Considering these last

two groups together, we see that the incidence of coronary disease in the group of smokers was relatively about three times that in the control group of non-smokers. Beyond 60 years of age no noteworthy differences were observed.

Although it was realized that the degree of smoking could be graded with only approximate certainty from the records, an attempt was made to see whether the data would reveal any correlation between the incidence of coronary disease and the degree of smoking. For this purpose the males between the ages 40 and 49 years were chosen, since it was in this group that the difference in incidence of coronary disease was most apparent. The nonsmokers were compared with the smokers, the latter grouped into those who were graded as smokers of degrees 1 and 2 and those who were graded degrees 3 and 4. The results are shown in table 3, in which it is seen that for nonsmokers, smokers of degrees 1 and 2 and smokers of degrees 3 and 4 the incidences of coronary disease were respectively 1.0 per cent, 4.6 per cent and 5.9 per cent. Although the numbers in each of the groups are too small to establish the rise in incidence of coronary disease with increasing degree of smoking in a "statistically significant" sense, the general rise in incidence with increasing degree of smoking is consistent with the other observations of this investigation.

TABLE 3.—Analysis of Influence of Grade of Smoking on Incidence of Coronary Disease

Males, Ages 40 to 49 Years, Inclusive Smokers and Nonsmokers			
Degree of Smoking	Total Cases	Coronary Disease	
		Number	Per Cent
None	208	2	1.0
1 to 2	174	8	4.6
3 to 4	31	2	5.9

COMMENT

In the interpretation of these statistics, certain facts must be borne in mind. The data were obtained from the records of a large clinic and cannot therefore be representative of material that could be derived from the general population, in which a lesser incidence of pathologic conditions obviously occurs.

However, from the material comprising this study it appears that a greater incidence of coronary disease occurs among smokers than among nonsmokers in the younger age group, that is, less than the age of 50 years and perhaps also among those in the age group 50 to 59 years (table 2). This, however, is not true in the older age groups. Furthermore, the incidence of coronary disease among patients less than 50 years of age was greatest among excessive smokers, was least among nonsmokers and occupied an intermediary position among moderate smokers.

It is therefore probable that the smoking of tobacco has a more profound effect on younger individuals owing to the existence of relatively normal cardiovascular systems, influencing perhaps the earlier development of coronary disease. In the older age groups, in which arterial changes are prominent regardless of extraneous influences such as smoking, the possible harmful effects of tobacco smoke are less evident than the other factors concerned in the production of atherosclerosis.

ABSTRACT OF DISCUSSION

DR. FRANCIS D. MURPHY, Milwaukee: The prodigious increase in consumption of tobacco after the first world war corresponds in time with the growing concern over diseases of the coronary arteries of the heart. The belief is spreading that the smoking of tobacco has an unfavorable influence on the course of coronary disease. However, White and Sharber in 1934 stated that the incidence of coronary heart disease is even higher in nonsmokers than in smokers. Therefore with particular interest I view the report of Drs. English, Willius and Berkson. From table 1 it appears that smoking has little influence on the incidence of coronary sclerosis. But there is a decided contrast between the 80 per cent incidence of smokers among patients with coronary disease and the 62 per cent incidence of smokers in a noncardiac group. Probably the authors' most striking observation concerned the incidence of coronary disease among nonsmokers, which was 1 per cent as compared with 6 per cent among heavy smokers. One may conclude from laboratory and clinical investigations and statistical reports that smoking is not an innocent habit; it may even be a contributory etiologic factor in coronary disease. Observations convince me that smoking is a distinct menace to patients with hypertension and coronary disease and that it may provoke an attack of angina and auricular fibrillation. When one of my patients, a physician, stopped smoking, the attacks left him but came back as soon as he resumed smoking. It is generally agreed that all patients with coronary disease should discontinue smoking; yet it must be recognized that there is great variation in individual patients' tolerance to tobacco. Some claim that smoking improves the coronary circulation and that attacks become less. In view of these facts one's advice should be tempered accordingly, but a rather strong case is being built up against tobacco, especially in individuals who are past 40 with evidence of coronary disease. This excellent report is a significant contribution to the subject of smoking and coronary disease from two points of view: First, the intrinsic value of the data submitted is of vital and practical importance; and second, it will stimulate others to make a comparative study of their own material in a similar way, so that a final appraisal of the influence of tobacco on the heart may be given.

DR. GEORGE R. HERRMANN, Galveston, Texas: It is only by impartial analyses of great masses of clinical material that is not available to many of us, of carefully studied patients, that we can hope to arrive at a fair-minded conclusion and an approximately true conception of the real effects of tobacco smoking. Drs. English, Willius and Berkson have selected what seems to be the most rational approach and have included proper controls as far as such are possible. In this study, as in most biologic statistical work, there are many minor variables that cannot be taken into consideration. The authors have had to omit many of these, which, if included, would probably have done nothing more than perhaps obscure the chief issue. Each one's own relatively and statistically insignificant experiences, especially recent, have a tendency to bias one. We see only the few sick smokers and lose sight of the great number of smokers who have no symptoms to cause them to consult us. We realize this fully, and yet we are likely to be obsessed and unduly influenced by our meager clinical experiences. The association of tobacco smoking in thrombo-angiitis obliterans and other vascular disease has greatly impressed those who have been interested in peripheral circulation. The question of what part is played by some patients' tendency to become sensitized to the drug, while most individuals develop a tolerance to it, might be raised even after this extensive study. It would be desirable to have in addition similar data on 1,000 smokers, all who feel dizzy or nauseated with the first smoking in the morning or whose extremities get cold and clammy or whose electrocardiograms show definite abnormalities during and following smoking, to be contrasted with data from 1,000 smokers who have a tolerance. That may have been taken into account. What percentage of these patients in each group were allergic? Are such patients more likely to suffer damage? Is one justified in insisting on absolute interdiction of the use of tobacco by all patients who have not developed a tolerance for the drug? These conditions should be indications for stopping smoking as well as anginal symptoms and coronary thrombosis.

We should be able to say before the age of 40 years what ones are likely to be in for trouble. What will be our criteria? Are we not justified in interdicting tobacco smoking in those who exhibit such abnormal reactions? Drs. English, Willius and Berkson demonstrated a significant and to my mind a most important fact, distinctly greater prevalence of demonstrable coronary artery disease among tobacco smokers in the younger age groups. Does this not suggest that the vascular reactions that are known to occur as a result of the pharmacologic effects of nicotine in susceptible individuals contribute to an earlier degenerative coronary artery disease? Must they not be stopped short of the development of such lesions?

DR. SOMA WEISS, Boston: This interrelationship between tobacco smoking and coronary disease is an important one. The public is particularly interested in it. While there is justified suspicion that there may be an interrelationship, a causative interrelationship, between these two conditions, we must carefully examine the evidence for such a conclusion. Granted that smoking was more prevalent statistically among the younger group with coronary disease, does that justify the conclusion that smoking was responsible or was a contributing factor to coronary disease. All one can say is that smoking was more prevalent, but the interpretation of this finding is difficult. For example, one may give the interpretation that the temperament of the hard-working individual who is predisposed to coronary artery disease would make him the type of individual who would also smoke, but the fact that he is smoking does not justify a conclusion that the smoking *per se* is a causative or even a contributory agent of coronary disease. I should like to find out from Dr. Willius whether or not my remarks are justified.

DR. WILLIAM D. STROUD, Philadelphia: We are grateful to Dr. Willius for this careful analysis, but I am wondering whether we are justified in concluding that tobacco can produce or increase the rapidity with which arteriosclerosis or atherosclerosis develops. It appears to me much like the subject of the athlete's heart. We feel today that the reason many athletes die in their fifties or sixties of coronary disease is not that they were athletic but that they were born with a spasmogenic aptitude. They seem to inherit from their ancestors the tendency toward hypertension which contributes toward their coronary disease. They most likely would have developed coronary disease at the same time whether or not they had been athletes. This has been borne out by studies of Harvard and Yale and Oxford and Cambridge crews, and especially by an experience of some five or six years ago, when a Harvard crew returned to college after some fifty years—all were over 70. They entered a shell and rowed down the Charles River. The only man in the crew who had died was the coxswain! He died of coronary thrombosis. I think it is the same thing with tobacco, and fortunately we have an excellent antidote, which is alcohol! I should like to ask Dr. Willius if he agrees that it is a possibility that these individuals are born with a tendency toward this condition and might develop it whether they smoked or not. I think we should differentiate distinctly between tobacco as an etiologic factor in this condition and as a factor in producing symptoms. If a person who has arteriosclerosis, hypertension or atherosclerotic changes uses tobacco to excess he will develop symptoms more quickly or more definitely while smoking, and they will disappear if he gives it up.

DR. FREDRICK A. WILLIUS, Rochester, Minn.: We gave this problem a great deal of thought. I tried to state cautiously in my introduction that we did not assume that tobacco smoke—and you will not that we carefully avoided the use of the term "nicotine" but said "tobacco smoke," because we have reasons to believe that probably more than the chemical agent nicotine plays a part, was etiologic but suggested the possibility, owing to these observations, that it was a precipitating influence in the earlier development of coronary disease. It is perfectly true, and we agree, of course, with Dr. Weiss and with Dr. Stroud that many other factors enter into the problem—heredity, our manner of doing things, temperament, and so on and so forth, these imponderables that undoubtedly play a tremendous part in our destinies as we go through life. We were aware of the fact that in presenting this subject it would be controversial and that at this time physicians are not yet ready to agree on this increasingly important subject.

SULFANILAMIDE IN THE TREATMENT
OF ERYSIPELAS

A CONTROL STUDY

JOHN A. FOLEY, M.D.

Clinical Professor of Medicine, Boston University School of Medicine
AND

ELTON R. YASUNA, M.D.

BOSTON

Several years have passed since the introduction of sulfanilamide into clinical medicine, and from the great mass of literature amassed concerning this drug certain claims have been made. Undoubtedly sulfanilamide is valuable in combating infections caused by certain organisms, especially the streptococcal groups of infections, which include the streptococcal pneumonias, wound infections and septicemias, scarlet fever and erysipelas. Concerning erysipelas, we have thought it worth while to review our cases in which sulfanilamide was administered at the Boston City Hospital during the past two and one-half years and contrast them with the cases without sulfanilamide in the preceding two and one-half years.

Erysipelas is a disease of the lymphatic system of the skin characterized by a slightly raised, sharply demarcated, tender red spreading indurated area. It usually involves the face, arising from a minor trauma or infection frequently overlooked by the patient, and spreads rapidly to form the characteristic "butterfly distribution" which includes both zygomatic areas and cheeks connected by the bridge of the nose. It often involves the legs, especially when varicose veins or other vascular disturbances are present; it may complicate operative wounds and more rarely may occur on other parts of the body. Hoyne¹ has shown that the disease is usually acquired through contact and that trauma, however slight it may be, is necessary for erysipelas infection although less than 60 per cent of patients with facial erysipelas admit a history of injury. On the other hand, whenever erysipelas appears on any other portion of the body there is almost invariably a history of trauma such as an abdominal operation, herniotomy, a varicose ulcer of the leg or a simple abrasion.

The etiologic agent can usually be isolated from the skin involved; it is found to be limited to the lymphatics of the skin and to possess the immunologic and cultural characteristics of Lancefield's group A.² Keefer and Spink² isolated twenty-two strains in their studies, all of which were of the human type (Lancefield group A) and produced beta hemolysis on blood agar.

Erysipelas is an acute disease, the onset usually characterized by a chill or chills followed in from one to three days by the appearance of the cutaneous lesion, which spreads rapidly. The temperature quickly rises to from 102 to 104 F., persists at a high level for from two to four days and then subsides by lysis to normal around the eighth day³ on the average. Occasionally

the temperature returns to normal by crisis, and more rarely the course is afebrile. The lesions of the skin fade after the first week but do not disappear until several days after the return of normal temperature. Local complications occur in the form of abscess, cellulitis or necrosis, while the more uncommon generalized complications appear as nephritis, septicemia, bronchopneumonia or meningitis.

In general, uncomplicated erysipelas is a self-limited disease, but in the presence of complications it may become a serious and occasionally fatal condition. Age plays an important role in prognosis, with infants below the age of 2 years and adults beyond the fifth decade showing a high mortality rate. Below the age of 2 from 37 to 75 per cent⁴ of all patients may be expected to die, while in the older age groups the death rate rises with the age. In the series of 998 patients analyzed by Hoyne, Wolf and Prim⁴ at the Cook County Hospital from 1934 to 1938 inclusive the mortality in the fifth decade was 5 per cent, in the sixth decade 12.9 per cent, in the seventh decade 17.6 per cent and in the eighth decade 45.5 per cent. Hoyne¹ has also analyzed the 5,666 cases from 1912 to 1933 and found an average mortality of 12 per cent in all ages, the extremes being 8.1 per cent and 18.2 per cent. Between the two extremes of life the death rate is from 3 to 7 per cent. The presence of complications such as renal damage, cardiac conditions, obesity, diabetes and pneumonia all lend themselves to a guarded prognosis. The finding of blood cultures positive for the hemolytic streptococcus is of grave prognostic significance, especially with infants, in whom a septicemia usually proves fatal. It is generally conceded that an attack not only fails to confer immunity but seems to render the individual more susceptible.

A multiplicity of therapeutic measures have been advocated in the treatment of erysipelas, but few have proved useful. Ointment of ichthammol was formerly employed but has been found to be valueless and had the disadvantage of concealing the true appearance of the disease. Then hot wet boric acid or magnesium sulfate dressings enjoyed a brief popularity, but they seemed to enhance the development of abscesses and were abandoned. Tincture of iodine or mercurochrome has never found a place in the treatment of this disease. It was thought that intracutaneous injections of 2.5 per cent phenol or 1:1,000 mercury bichloride would be valuable in controlling the spread of the infection, but these were complicated by sloughing or poisoning in a number of cases and have been discontinued. Along these same lines nonflexible collodion has been suggested. The collodion was painted on the skin at least 1 inch beyond the margin of the lesion in an attempt to halt an advancing erysipelas. Some success has been obtained by the use of this method and it is still used occasionally.

Iced magnesium sulfate or boric acid applications applied locally have been used for many years, and it is felt that some relief of pain with fewer complications has been obtained. Ultraviolet and roentgen treatments to the lesions have also been found to be beneficial. Local applications of various antiviral creams have been suggested.

Birkhaug⁵ in 1926 first showed that the hemolytic streptococcus of erysipelas had a specific toxin which could be neutralized by an antitoxin. During the next few years serum was perfected, concentrated and used extensively. Symmers and Lewis⁶ at Bellevue Hospital are probably the outstanding advocates of serum. They have reported a series of 4,698 cases in which antitoxin was administered between 1927 and 1934. In their adult series their mortality was 6.9 per cent with antitoxin as compared with 9.2 per cent without antitoxin, while for infants the figures were 14 per cent mortality with antitoxin and 47.5 per cent without antitoxin. They felt that five out of 100 patients receiving the serum were not benefited because of the various strains of streptococcus causing erysipelas. Most observers⁷ who analyzed their results with serum felt that the mortality rates were diminished. However, in 520 cases McCann⁷ concluded that antitoxin had no effect on the course of the disease. His ten year study showed a mortality rate of 13 per cent with 58 per cent of patients having extensions of lesions in the serum treated group as compared with 15.5 per cent mortality and 35 per cent extension in the control group of 558 patients. Francis⁸ could not confirm the finding of soluble toxin in the circulating blood of patients with erysipelas as claimed by Birkhaug.⁵

During the past three years sulfanilamide has been used extensively in the treatment of erysipelas, and the majority of reports have been favorable. Snodgrass and Anderson⁹ compared 106 cases of erysipelas treated with sulfanilamide with a control group in which ultraviolet radiation was used. In 76 per cent of the drug treated patients the temperature was normal within forty-eight hours while only 48 per cent of the ultraviolet group had this result. Recurrences, complications and deaths were all significantly less with sulfanilamide therapy.

Meyer-Heine and Huguenin¹⁰ studied 150 cases treated with approximately 2 Gm. of sulfanilamide daily and regarded the drug as a specific therapeutic agent. In 98.5 per cent of their cases the course was one of rapid fall in temperature with subsidence of the local lesion within forty-eight hours. There were no deaths and few local complications.

Nelson, Rinzler and Kelsey¹¹ compared results in 344 sulfanilamide treated cases with the results for over 4,000 other cases in which various other therapies had been applied. They found the duration of fever to be shortened from 6.8 to 4.2 days, the mortality rate from 8.0 to 1.9 per cent and the hospital stay from 11.0 to 6.9 days. Forty-four per cent of their patients had a normal temperature within forty-eight hours, and only 3 per cent had local complications. The 382 adults treated with erysipelas antitoxin in their series

had a mortality rate of 9.2 per cent, an average hospital stay of 11.1 days and febrile period of 6.8 days.

Favorable results with sulfanilamide have also been obtained in small series by Peters and Havard,¹² Toomey,¹³ Hageman and Blake,¹⁴ Frankl,¹⁵ Breen and Taylor,¹⁶ Kramer¹⁷ and Rantz and Keefer.¹⁸

ANALYSIS OF CASES

We have studied the eighty patients with erysipelas admitted to our wards at the Boston City Hospital from June 1937 through December 1939 who have been treated with sulfanilamide and have compared them with the eighty preceding patients who did not receive sulfanilamide. This "control group" includes patients admitted from January 1935 to June 1937.

In general the patients entering the hospital during the past five years have been of the same social status with about the same environmental factors. The prognosis of erysipelas in the aged is comparatively poor, and in our series the average age in the control group is less than in the sulfanilamide group, 47 years and 52 years respectively. Thirty-six per cent of the patients in the control group as contrasted with 48 per cent of the sulfanilamide group were over 50 years of age, a decided advantage for the control group. Debilitating diseases such as heart disease, generalized arteriosclerosis, parkinsonism, emphysema, pneumonia, alcoholism and diabetes are known to modify the course of the disease unfavorably. One or more complicating diseases were present in fifteen (19 per cent) of the control group and in twenty-seven (31 per cent) of the sulfanilamide group. Blood cultures were done in only a small percentage of cases and so cannot be analyzed.

In the control group seventy patients had lesions which involved the face or ears, nine the legs and one the back, while in the sulfanilamide group sixty-nine patients had involvement of the face or ears, nine of the legs or thighs and two of the arms. The seasonal incidence in the two groups was about the same.

All patients in both the control and the sulfanilamide group received a fairly constant type of treatment consisting of forced fluids, catharsis, local applications of iced magnesium sulfate and symptomatic therapy. The average dose of sulfanilamide was 7 or 8 Gm. the first twenty-four hours and 5 or 6 Gm. each twenty-four hours thereafter. The average duration of the drug therapy was 4.5 days, with extremes of one and eight days.

In evaluating the results we used certain criteria which we felt would best demonstrate the comparison in an objective manner. These criteria were the duration of fever, the average hospital stay, the incidence of complications and the mortality. Accurate data as to the duration of the cutaneous lesions were not available.

The average duration of temperature from the time of admission to the return to normal of the drug treated patients was 2.94 days, as shown in the table. The

decline in temperature was progressive in almost all cases, usually taking the form of rapid lysis, and rarely was a recurrence seen following the institution of sulfanilamide. In the control group the average duration of temperature was 4.74 days, and in this group the temperature frequently rose on the second or third day to a new high level before returning to the base line. The average admission temperature was 102.2 F. in the control group and 101.8 F. in the treated group, with extremes of afebrile states and 105 F.

The average hospital stay of the drug treated group was 10.0 days, as compared with 12.9 days for the control group. In a small number of cases the hospital stay was markedly prolonged by factors unrelated to the erysipelas, and in these instances the hospital stay was calculated from the duration of the course of the erysipelas. The duration of hospitalization of patients receiving sulfanilamide was therefore shortened by almost three days, this time representing a substantial saving of time by the patient and of money by the hospital.

Seven patients (9 per cent) in the sulfanilamide group had complications, two of which ended fatally. The two deaths were similar in type, the patients having persistent oliguria and dying of uremia. Other complications consisted of infectious arthritis in two cases

Results of Sulfanilamide Treatment in Erysipelas

Course in Hospital	Sulfanilamide-Treated Subjects	Controls
Average duration of temperature.....	2.94 days	4.74 days
Average hospital stay.....	10.0 days	12.9 days
Complications.....	7 cases (9%)	18 cases (22%)
Mortality.....	2 cases (2.5%)	8 cases (10%)

and one each of parotitis, periorbital infection, infected wen and pneumonia. In no instance was there a spread of the lesion, although this was watched for carefully. In the control group complications developed in eighteen cases (22.5 per cent), eight of which ended fatally. Ten patients exhibited a definite spread of the lesion to adjacent areas, usually the ears, forehead and neck. One of these contracted a Streptococcus haemolyticus septicemia and died, while another became very toxic, with a high temperature and disorientation, and died. The remaining eight patients recovered. Other complications consisted of four cases of pneumonia, all ending fatally, three cases of abscess of the eyelid with recovery, one case of nonfatal nephritis and one case of probable lateral sinus thrombosis with death.

The mortality rate was 2.5 per cent in the drug treated group and 10.0 per cent in the control series. One patient treated with sulfanilamide had made a complete recovery and was awaiting discharge when she suddenly dropped dead. Autopsy revealed a large pulmonary embolism. This case was not included in the mortality rate. In the control group one patient had erysipelas and made a fair recovery only to die a few weeks later from cardiac decompensation. This case was not included in the mortality figures.

No severe blood dyscrasia such as hemolytic anemia or granulocytopenia was experienced among the eighty patients receiving sulfanilamide. Cyanosis, nausea, anorexia, moderate malaise and mild anemias were frequently encountered, but in no instance were any of these sufficiently severe to warrant discontinuance of the drug.

COMMENT

It has been repeatedly shown that the action of sulfanilamide on the hemolytic streptococcus in vitro is one of bacteriostasis¹⁹ with almost no bactericidal effect. To obtain bacteriostatic effect, however, adequate concentration of the drug must be maintained in the blood as shown by Long and Bliss¹⁰ and Colebrook and his associates¹⁹ in mice. These workers have shown that the withdrawal of the drug would then cause these animals to succumb, presumably because active immunity against the organism failed to develop. To apply this work to man, we found in our group of cases that the temperature returned to normal in about three days. The drug was discontinued after 4.5 days on the average (with extremes of one and eight days). If the work in mice applied to human beings, one would expect a certain number of patients to have relapses on stopping the drug since little or no active immunity would be developed by the patient during sulfanilamide therapy. Actually, this did not occur in a single instance, and therefore it seems probable that active immunity is developing during sulfanilamide therapy and that this immunity protects the patient on withdrawal of the drug.

It has been held by some¹⁸ that sulfanilamide cannot be expected to effect immediate cures in erysipelas since the development of immune bodies must be awaited. It is further stated that the fall in temperature in erysipelas is presumably due to the development of antistreptococcus immune bodies in the afflicted individual. If this were so one would expect a return to normal temperature about the same time in uncomplicated cases with sulfanilamide treatment and control cases, since the immune body production is apparently the same in the two groups. On the contrary, however, the return of the temperature to normal was 2.9 days with sulfanilamide as contrasted with 4.7 days in the controls. Spink and Keefer²⁰ have shown that the height of anti-streptolysin titer is obtained within the first twenty days and may remain elevated from forty days to six months. Moreover, they found no relation between the time of recovery and the presence of increasing amounts of antibodies in the blood.

Analysis of average hospital stay, duration of fever, incidence of complications and mortality rates all favored the sulfanilamide treated group, as can be seen in the table. In addition, the control group represented the more favorable cases from the point of view of prognosis, since the average patient was five years younger than in the sulfanilamide group, and the incidence of complicating medical diseases was lower. Thus it appears that the patient with erysipelas who receives sulfanilamide will have a more benign course with much less chance of developing complications than the untreated patient.

A few words should be said about the cases ending fatally. In the control group all the deaths resulted from overwhelming toxic infection due to erysipelas

20. Spink, W. W., and Keefer, C. S.: Studies of Hemolytic Streptococcal Infection: II. The Serological Reactions of Blood During Erysipelas, *J. Clin. Investigation* 15:21-35 (Jan.) 1936.

with a terminal complication such as septicemia or pneumonia which accelerated the death. In the sulfanilamide group no case of overwhelming infection was seen. Two deaths did occur but they were of a different type from those seen in the untreated group. These cases require special comment:

CASE 1.—A woman aged 34 was admitted to the hospital April 19, 1939, with typical facial erysipelas involving the nose, both cheeks and part of the forehead. The admission temperature was 100.4 F. and the patient did not appear toxic. She was given sulfanilamide 90 grains (5 Gm.) a day for six days, and the temperature returned to normal by the third day. The facial lesion started to recede. By the fifth day the erysipelas had subsided almost completely, but oliguria developed. Vigorous efforts to overcome this with parenteral fluids without salt, 50 per cent dextrose given intravenously and sodium bicarbonate intravenously were all unsuccessful. The nonprotein nitrogen level rose progressively from 50 mg. to 240 mg. per hundred cubic centimeters. The temperature remained normal except for the last two days, and a Mosenthal test showed inability to concentrate the urine. The patient had a uremic type of death on the seventeenth hospital day. Permission for autopsy could not be obtained.

CASE 2.—A woman aged 67 entered the service with a three day history of facial erysipelas. Sulfanilamide was given for forty-eight hours and then discontinued because of oliguria. The facial lesion did not spread and the temperature returned to normal in two days, but the patient remained drowsy. It was found that the nonprotein nitrogen values were rising, and forced parenteral fluids were given unsuccessfully. Urinalyses were suggestive of nephritis, and the patient had a uremic death on the eighth hospital day. Autopsy revealed large engorged red kidneys; the microscopic sections are still being studied.

It is interesting to note that both patients had a renal death. In one case the facial erysipelas had cleared, and in the other it was under control. The question arises whether the kidney shutdown was caused by the disease or by the sulfanilamide. The answer cannot be given at present, but further work is being done along these lines. Perhaps poor kidney function is a contraindication in the use of sulfanilamide.

SUMMARY AND CONCLUSIONS

In eighty cases of erysipelas sulfanilamide treatment was given and the results were compared with those in eighty similar cases in which sulfanilamide was not used.

It was found that the drug treated patients returned to a normal temperature almost two days earlier than the controls.

The hospital stay was shortened three days for the sulfanilamide treated patients.

Complications occurred twice as frequently in the control group as in the treated group.

The mortality rate in the sulfanilamide group was one fourth that of the untreated group.

Two patients in the erysipelas group died in uremia from kidney shutdown after the erysipelas had been brought under control. It is possible that they represent complications of sulfanilamide.

Twelve Calories for Every Pound of Body Weight.—

A man lying quietly in bed throughout the twenty-four hours of the day uses at least twelve calories for every pound of body weight, which means for an average man a daily total of from 1,600 to 1,800 calories.—Rose, Mary Swartz: Feeding the Family, New York, Macmillan Company, 1940.

VERATRUM VIRIDE IN THE TREATMENT OF ECLAMPSIA: II

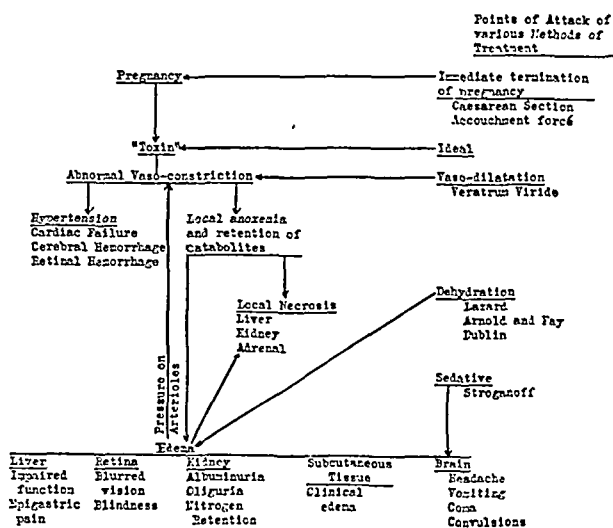

RICHARD D. BRYANT, M.D.

AND

JOHN G. FLEMING, M.D.

CINCINNATI

In 1935, one of us¹ reported a series of cases of eclampsia treated at the Cincinnati General Hospital during the previous ten years. The use of the vaso-dilating drug veratrum viride was stressed. Previously this drug had been used with success by Dr. William Gillespie as chief of the obstetric service until his death in 1925. Since then under his successor, Dr. H. L. Woodward, and his attending staff details of the management of eclampsia have been further refined and improved. Since 1930 there have been but minor variations in the treatment. We believe that a sufficient number of cases have been treated successfully to justify the conclusions that veratrum viride is an extremely valuable adjunct in the management of eclampsia and that the drug itself is not a source of

Theoretical sequence of events in eclampsia.

danger to the patient (as is stated in a current standard textbook) if used in therapeutic doses.

The present series includes 120 cases. Fifty-four of the cases were embraced within the previous communication, but in order to group the entire series in which the same standardized treatment was used they are here combined with the sixty-six cases treated since 1935. There were only two deaths in the entire series, a mortality rate of 1.67 per cent.

Since the previous communication considerable experimental, clinical and pathologic evidence has accumulated to confirm our earlier stated belief that many, if not all, of the phenomena which make up the clinical picture of eclampsia are immediate or remote consequences of abnormal vasoconstriction of the entire arteriolar tree. As a result a therapeutic agent used empirically for many years now stands forth in the light of newer knowledge as eminently rational. The

accompanying chart illustrates graphically a theoretical sequence of events in eclampsia, as well as the point of attack of various popular methods of treatment.

In antepartum and intrapartum eclampsia, immediate termination of the pregnancy has been almost abandoned because of the very high mortality rate following this

procedure. The ideal method of treatment would be to neutralize or counteract the so-called toxin produced by the pregnancy and resulting in generalized vasoconstriction and eclampsia. Because no such "toxin" has been demonstrated, this method cannot be followed. We feel that the treatment discussed in this and the previous paper attacks the disease process as near its source as present knowledge and technic permit. Treatment by either dehydration or sedation alone appears to be purely symptomatic.

Division of the cases in this series on the basis of initial convulsions in relation to labor is shown in table 1.

The greatest difficulty was encountered, naturally, in the antepartum group of cases, in which the problem of induction of labor was added to the purely medical problem of management of the acute eclamptic state. The intrapartum cases were somewhat less difficult; the labor and delivery were treated conservatively, as if the patient were not toxic. The second stage was shortened, if indicated, when reasonably safe and easy. The postpartum cases were the least difficult to treat, as the only problem was the control of, and prevention of further, convulsions.

* Two ounces (60 cc.) of castor oil and 15 grains (1 Gm.) of quinine in divided doses, followed by a hot enema.

† Sterile vaginal examination with digital separation of membranes from the lower uterine segment.

The methods of inducing labor in the fifty-six antepartum cases are shown in table 2.

It might have been possible in many cases of antepartum eclampsia to carry the patient for days or even weeks, until labor set in spontaneously. However, with rare exceptions, this procedure was wholly impracticable because of the prolonged hospitalization necessary for the close observation required. In general, then, termination of the pregnancy represented the final step in the treatment of antepartum eclampsia.

The induction of labor was regarded as a gradual and progressive process, with as little regard as possible for definite time limits. It was observed that, if sufficient time was given to proper treatment of the complicating eclamptic state, labor often ensued spontaneously. Uterine contractions set in spontaneously in thirteen, or 23.2 per cent, of the cases of antepartum eclampsia in this series (table 2).

The biggest single factor influencing the decision to induce labor was the general condition of the patient. Ideally, we believe, no really active induction should be undertaken until there are complete return of consciousness, absence of all subjective symptoms, diminishing edema and an adequate output of urine, with a decrease in albuminuria and the number of casts. The blood pressure level is not of itself of paramount importance if the aforementioned conditions are met. However, in most cases it seemed safe and even wise to begin what we consider preparatory steps for induction of labor even before complete control of the toxemia was achieved.

In this series the elastic bag was the most effective agent for inducing labor. However, because its use involves intravaginal and intra-uterine manipulation and because a certain amount of cervical dilatation is required before it can be used, other and simpler pro-

TABLE 3.—Antepartum Eclampsia Requiring Induction of Labor: Time Required to Achieve Complete Control of Convulsions

cedures were usually tried first. These procedures might be called preparatory, although they themselves sometimes brought on labor. Labor occurred spontaneously in 23.2 per cent of the cases, the only manipulation having been a simple rectal examination or several repeated examinations. Medical induction, consisting of administration of castor oil, quinine and a hot enema, was next tried. If labor had not begun after twenty-four hours, the cervix was usually found to have benefited from the increased pelvic congestion, as indicated by softening of the cervix and shortening of the cervical canal.* The membranes were then stripped away from the lower segment by sterile vaginal examination, and this was followed by medical inductive measures. If these measures failed, after another twenty-four hours they were repeated or the membranes were ruptured. If conditions were not favorable for rupturing the membranes, and if cervical dilatation of at least one fingerbreadth was present, a bag was introduced extra-ovularly. In either case labor soon ensued. The membranes were always ruptured when the bag was expelled and delivery was awaited expectantly. A long, hard, closed cervix, usually in a primipara, occasionally proved intractable to the aforementioned preparatory measures. Rarely it was necessary to pack the cervix for twenty-four hours before a bag could be introduced. Instrumental dilation of a closed cervix for the purpose of achieving enough dilatation for introduction of a bag was not resorted to because of the danger of tearing rather than dilating the cervix.

We regard this progressive preparation for the induction of labor as one of the fundamental factors in the management of antepartum eclampsia and one which must be observed if good results are to be obtained. In the forty-three cases of antepartum eclampsia in this series requiring induction of labor, the average interval

between the apparent control of convulsions and the initial attempt to induce labor was fifty-seven hours and fifty-two minutes. In the same group of cases the average interval between the initial attempt at induction and delivery was forty-eight hours and forty minutes. The sum of these two figures, 106 hours and thirty-two minutes, or almost four and a half days, represents the average interval between the time when the convulsions were apparently under control and delivery. While termination of the pregnancy remains an essential feature of the management of antepartum eclampsia, we believe that a happy outcome depends in a large measure on the choice of the proper time for undertaking this potentially dangerous operation.

The difference between the radical management of antepartum eclampsia and the induction of labor as used in this series of cases lies in the timing of termination of the pregnancy and the purpose for which it is done. With the radical treatment the baby is delivered for the express purpose of stopping the convulsions; with conservative methods of treatment, such as the one under discussion, the pregnancy is terminated only after the eclampsia is well controlled and for the purpose of preventing recurrence of the entire acute toxic state. Any method of treatment using the latter principle must therefore include measures which completely control the acute toxemia and maintain control for as long a

TABLE 5.—*Entire Series: Time Required to Achieve Complete Control of Convulsions*

No convulsions after treatment was started	74	61.7	61.7
Convulsions controlled within 15 minutes...	15	12.5	74.2
Convulsions controlled within 30 minutes...	8	6.7	80.9
Convulsions controlled within 60 minutes...	3	2.5	83.4
Longer than one hour required.....	20	16.6	
	120	100.0	

period as is necessary. That this objective was accomplished with marked success in the cases of antepartum eclampsia in which induction of labor was required is demonstrated in table 3.

To this factor—the ability to maintain complete control of the eclampsia until labor could be induced under advantageous conditions, even when a number of days were required—may be attributed much of the success obtained with antepartum eclampsia in this series.

For the entire series of 120 cases, the figures on the control of convulsions are interesting, as revealed in tables 4 and 5.

At delivery, operative methods were reduced to a minimum because of the increased susceptibility to infection and the low tolerance to prolonged anesthesia characteristic of eclamptic patients. The methods of delivery in the entire series of cases is shown in table 6.

Infections occurred considerably more frequently than in the average obstetric census. Following the accepted standards of morbidity, table 7 reveals this increased morbidity rate.

Only two deaths occurred among the 120 cases in this series, a mortality rate of 1.67 per cent. Both presented unusually difficult problems, as a summary of their clinical course shows.

REPORT OF CASES

CASE 1.—A Negress, aged 19, a primipara near term, was admitted to the hospital in coma after having had five convulsions at home and en route to the hospital. The blood pressure on admission was 170 systolic, 130 diastolic, and a catheterized specimen of urine showed 3 plus albumin. Our standard medical treatment for eclampsia was instituted. Two

minutes after treatment was started a convulsion occurred. There were no further convulsions, and the toxemia per se offered no major difficulty. Forty-eight hours after the last convulsion a vaginal examination revealed a long closed cervix. A medical induction resulted only in false labor. On the fifth day the cervix and lower uterine segment were packed. After twenty-four hours the temperature rose to 103.8 F. and the pack was removed. On the seventh day the cervix was still firm and edematous and dilated but one fingerbreadth. An attempt to insert a Braun bag was unsuccessful, although fairly good labor pains ensued. Twenty-four hours of labor produced no change in the cervix.

Finally, 163 hours after the last convulsion, the cervix was dilated manually and a stillborn baby was delivered by high forceps. Bilateral cervical lacerations and a deep perineal and sulcus tear resulted. On the second day post partum the temperature began a septic rise and on the fifth day there was a moderate postpartum hemorrhage from the necrotic cervix and perineum, requiring secondary suturing. Thereafter the course was that of fulminating sepsis, death occurring on the fourteenth day post partum.

The principal postmortem observations were acute endocervicitis and endometritis, with multiple secondary pulmonary abscesses and generalized sepsis. Marked degenerative changes, consisting of both central and midzonal necrosis, were present in the liver. The kidneys showed only toxic changes, mainly cloudy swelling of the tubules.

CASE 2.—A Negress, aged 42, a secundipara pregnant for the fourth time (approximately eight months), was admitted to the hospital in acute cardiorespiratory distress. Three previous

pregnancies had resulted in a miscarriage and two stillbirths. There was a history of severe asthma and of irregular anti-syphilitic treatment. The blood pressure was 210 systolic, 76 diastolic; there were 3 plus albumin and massive peripheral edema. Because the major features were those of acute cardiac failure rather than of acute toxemia, the patient was transferred to the medical service, where venesection and digitalization brought little improvement. Twenty-four hours after the administration of mercupurin (a mercurial diuretic) the patient had a generalized convulsion. Antieclamptic treatment was instituted and no further convulsions occurred.

On the fourth day after admission the membranes ruptured spontaneously. Labor failed to set in after two attempts at medical induction, so a bag was inserted. The patient's heart failed to respond to treatment and an oxygen tent was required throughout labor. Finally a stillborn baby was delivered by version and extraction (after attempted high forceps delivery) on the seventh day after the convulsion. The placenta failed to separate, and a brisk hemorrhage necessitated manual removal of the placenta.

During labor the temperature rose to 105 F. and thereafter continued a variable septic course. On the twenty-fifth day post partum a left gluteal abscess was incised and drained, and on the forty-ninth day a left subphrenic abscess required the same treatment. After this the course was rapidly downhill, with evidence of generalized peritonitis. On the sixty-fifth day post partum a right subphrenic abscess was drained. The patient failed to rally and died seven hours later.

TABLE 7.—*Entire Series: Morbidity**

Hospital Deliveries	Number of Cases
No morbidity	48
Morbidity	31
One day fever	18
Intrapartum fever	6
Intrapartum fever plus morbidity	4
Intrapartum fever plus one day fever	4
Admitted post partum	111
Total	9
	120

* No morbidity: temperature remaining under 100.4 F. after the first 24 hours post partum.
